Abstract

The Eastern Gabbro forms the northern and eastern margin of the Coldwell Alkaline Complex. It contains three rock series: the barren meta-basalt, the Layered Series, and the Marathon Series which hosts all known PGE mineralization. The Marathon Series can be distinguished from other Series using the combination of portable X-ray fluorescence (pXRF) and benchtop scanning electron microscope (bSEM). Whole-rock Ba, Mg# (molar $\text{Mg}/(\text{Mg}+\text{Fe}) \times 100$), Zr and V/Ti values acquired from pXRF, and Mg#s of olivine and clinopyroxene, and anorthite content (molar $\text{Ca}/(\text{Ca}+\text{Na}) \times 100$) of plagioclase acquired from bSEM-EDS are key parameters. The Layered Series generally contains higher Ba and lower V/Ti than the Marathon Series and presents relatively smooth normal and reverse differentiation trends, whereas the Marathon Series exhibits strong compositional changes over short distances.

Reverse and normal lithogeochemical and mineral chemical evolution are observed for the Layered Series at Four Dams and Area 41. Olivine-clinopyroxene Fe/Mg exchange disequilibrium is also observed, and is interpreted to reflect crystallization in an open dynamic system. Geochemical modeling shows that the Layered Series magma is more evolved than the Coubran basalts, but the former contains lower Pd+Pt contents than the latter. Cu-rich & PGE-poor mineralization is also recognized in the Layered Series at Four Dams. This is interpreted to reflect an early sulfide saturation of the Layered Series.

Area 41 is a newly discovered zone of mineralization at the northern edge of the Eastern Gabbro. Three types of mineralization are identified. Type 1 is Cu-rich but PGE-poor mineralization. Type 2 contains PGE mineralization and has mantle-like Cu/Pd ratios, suggesting that it likely formed in a relatively closed system, similar to the Main zone mineralization at the Marathon deposit. Type 3 mineralization is the most PGE-enriched and has low Cu/Pd ratios. This, together with average S/Se

ratios of 1200 is evidence of S loss, which suggests that it formed by multi-stage dissolution upgrading, similar to the W-horizon mineralization at the Marathon deposit. 3D modeling of the igneous stratigraphy and mineralization indicate that Area 41 is a magma conduit, similar to the Marathon deposit. Thus, the Coldwell may also contain additional conduit-related mineralization.

Key word: Coldwell Alkaline Complex, Eastern Gabbro, Cu-Pd mineralization, pXRF, benchtop SEM

Co-Authorship

This thesis consists of six chapters, four of which are in manuscript format. Chapter 3 has been published by *Geochemistry: Exploration, Environment, Analysis*. Chapters 4, 5, and 6 have yet to be submitted. In each of these manuscripts the thesis advisor R.L. Linnen is the second author. His role in the preparation of these manuscripts consisted of organization of research themes, supply of insightful suggestions and critical evaluations, and discussion of the data and my conclusions. Dr. D.J. Good and I.M. Samson are my thesis committee members, who contributed to the development of research questions and editing, as well as critical evaluation of each manuscript within this thesis. They are listed as the third and fourth author, respectively, on any subsequent publications originating from this thesis. R. Epstein was listed as the fifth author in the manuscript of Chapter 3. As a local geologist working on the Coldwell Alkaline Complex, her role in preparation of this chapter included help with rock identification in the field, and critical evaluation pertaining to the geological interpretation part proposed in this manuscript. I collected all of the powders and rock samples used in my thesis during field work in 2013 and 2014, except where noted. Thin section petrography and mineral chemical results including those from benchtop SEM-EDS and electron microprobe were conducted by me. Most whole-rock major and trace element abundances were determined at ALS mineral divisions at Vancouver and Thunder Bay. Additional whole-rock exploration assay data were provided by Stillwater Canada Inc.

Acknowledgements

I would like to express my sincere appreciation to my supervisor, Dr. Robert Linnen. This project would not have been possible without his scientific and financial support and immense knowledge and guidance in my research and writing. My sincere appreciation also goes out to Dr. David Good, who introduced me the Coldwell Alkaline Complex and taught me a lot of knowledges that helped this thesis greatly, without his help this thesis would take way longer. This project was funded by a NSERC grant of Dr. Iain Samson from Windsor, who also acts as my thesis committee member and offers me many insightful suggestions during the course of this thesis study, this deserves a great appreciation. It was great to work with such a dedicated team and I benefited greatly from the variety of backgrounds and specialties each of them possesses. China Scholarship Council (CSC) provided me a funding that covered my 4-year living stipends at Western, which is appreciated as well.

I would like to thank Stillwater Canada Inc. and John McBride for providing me the fieldwork opportunities for two summers, allowing me to gain further experience in exploration geology in addition to gathering samples for this project. I want to thank Rachel Epstein, without her help I am not sure if I would have been able to distinguish between all the gray rocks in Marathon. My thanks also go to Matthew Brzozowski, Ryan Ruthart, and Katrina McLean for assistances during the field work.

I am thankful to Dr. Charles Wu who taught me the principle of XRF technique and trained me how to operate the pXRF instrument at the very beginning of this thesis. I also would like to express my thanks to Marc Beauchamp for assistances of electron microprobe analyses, and to my lab mates Alysha McNeil and Abdullah Aseri for the help and countless discussions when working in the lab. The pXRF

and benchtop SEM-related work received many supports from the Elemental Controls Ltd. and JEOL, both are thanked here.

I would like to extend my gratitude to my parents and sister for their constant love, support, and encouragement. Last, but not least, I want to express my deepest acknowledgement to my dear wife, Xiaolei Liu, for her extreme patience and encouragement during this long time of thesis study.

WDS	wavelength-dispersive spectrometer
XRF	x-ray fluorescence

Chapter 1

Introduction

1.1 General introduction

The platinum group elements (PGE: Pt, Pd, Ru, Rh, Os, and Ir) are valuable and important in modern society due to their scarcity and use in technological applications. Their stable electrical properties, chemical resistivity, high melting point, as well as other unique physical and chemical prosperities make them ideal for jewelry and indispensable to modern technology and industry. Generally, the uses of PGE (particularly for Pd and Pt) are focused in autocatalyst, electronics, and jewellery, with relatively minor contribution in investment, glass, chemical, petroleum, and other (British Geological Survey Platinum, 2009, www.bgs.ac.uk). Over the last decade, the growing demand for Pt and Pd in industry, e.g., catalytic converters used for cars, led to the dramatic increase in the prices of PGE, from around US\$400 per oz for Pt in the 1900's to US\$2276 per oz for Pt by March, 2008 (British Geological Survey Platinum, 2009, www.bgs.ac.uk). The increases in prices in turn resulted in a worldwide PGE exploration boom. However, by far, the majority of the worlds supply of PGE is extracted from a few deposits within the Bushveld Complex of South Africa, with smaller contributions from the Stillwater Complex of the United States of America, and the Lac des Iles deposit of Canada, etc. (Maier et al., 2003; Fig.1-1). The question of whether other significant PGE deposits will be found in traditional PGE exploration settings has been increasingly asked by people from both industry and academia.

To aid in the search for other deposits, it is important to understand the processes involved in their deposition. How to explore for PGE in a more efficient and economic manner is another challenge that the mineral exploration industry is facing. The Coldwell Alkaline Complex is an excellent location to investigate mineralization processes and exploration protocols because: 1) the complex hosts several zones of PGE-enriched mineralization, notably the Marathon Cu-PGE

deposit; 2) the geology of the Coldwell Alkaline Complex is relatively well understood; 3) some geochemical exploration tools for the Coldwell Alkaline Complex have been developed (e.g., Good et al., 2015); 4) there is a large database consisting of over 40,000 assays from over 750 drill holes available (Good et al., 2015) for testing hypotheses and generating interpretations; and, 5) the igneous rocks of the complex are relatively pristine and undeformed, offering a good opportunity to study the magmatic process and associated mineralization. There are three main questions that will be addressed in this thesis.

Figure 1-1. Global distribution of major magmatic platinum group elements sulfide deposits, modified after British Geological Survey (2009).

Problem I: One of the key components to mineral exploration at the Coldwell Alkaline Complex is to distinguish between the different series of gabbros because only the Marathon Series is known to host PGE mineralization; whereas other series (e.g., the meta-basalt and the Layered Series) units lack PGE mineralization. However, in the field it is difficult to distinguish between the different series of gabbro units at the Coldwell Alkaline Complex. Particularly, the oxide augite melatroctolite and oxide melatroctolite are petrographically nearly identical, but

only the oxide melatroctolite belongs to the Marathon Series, and is host to some PGE mineralization. The distribution of the different series gabbro units is further complicated by block faults. Using lab-based analyses, Good et al. (2015) demonstrated that different igneous series units are geochemically distinctive, indicating geochemistry is a reliable tool to help distinguish the Marathon Series from other igneous series units. The geochemistry of samples traditionally determined by laboratory-based analyses involves a time delay and a relatively high cost and are therefore not suitable for decision-making in the field. Therefore, there is a need to establish some geochemical methods that can be used directly in the field to distinguish the three series units and help mineral exploration.

Problem II: The Layered Series constitutes the largest part of the Eastern Gabbro of the Coldwell Alkaline Complex, but it has received little scientific scrutiny due to the lack of PGE mineralization in this series. Understanding the characteristics and origin of the Layered Series is significant from at least three perspectives.

First, the PGE-barren nature of the Layered Series at this complex is in contrast to other PGE bearing stratiform or stratabound reefs within layered mafic-ultramafic intrusions, e.g., the Merensky Reef, UG2 chromite of the Bushveld Complex, South Africa (Armitage et al., 2002), the JM reef of the Stillwater Complex, Montana (Todd et al., 1982), etc. It is thus meaningful to investigate why the Layered Series at the Coldwell does not contain PGE mineralization. To answer this question, the genesis of the Layered Series must first be understood.

Second, knowing the characteristics and the origin of this intrusion may help in the interpretation of the early magmatic history of the Coldwell Alkaline Complex. It is, however, not clear what magma chamber processes that generated the Layered Series and their relevances to PGE mineralization. Particularly, Shaw (1997) observed both the normal and reverse evolution of the Layered Series gabbro at the Bamooos and Highway traverses of the Eastern Gabbro, but did not provide a

satisfactory explanation. To understand the genesis of the Layered Series, the origin of the reverse evolution must be explained.

Third, the PGE mineralization related Marathon Series is younger than the Layered Series, but both are petrographically similar and spatially close within the complex. However, it is not clear whether or how the Layered Series and the Marathon Series are genetically related, e.g., the same source, the same parental magma with different modifications, etc.

Problem III: It is unclear whether there is a general exploration model applicable for the whole Coldwell Alkaline Complex. According to previous studies, e.g., Ruthart (2013) and Good et al. (2015), mineralization at the Marathon deposit (the largest deposit within the Coldwell Alkaline Complex) can be explained by a conduit-type setting. It is, however, unclear mineralization elsewhere within the Eastern Gabbro is also conduit related. But knowing mineralization is conduit-related is meaningful because it predicts that mineralization can occur at different stratigraphic horizons and also increases the possibility for extreme PGE concentrations as a result of upgrading by a ‘multistage dissolution upgrading’ process (Kerr and Leitch, 2005). To investigate this, a relatively newly discovered Cu-Pd zone called Area 41, located at the north edge of the Eastern Gabbro, was examined in Chapter 6, with focuses on its igneous stratigraphy and mineralization processes. All the two perspectives at Area 41 were compared to those at the Marathon deposit to evaluate whether a conduit-type setting is applicable for PGE mineralization in the whole Coldwell Alkaline Complex.

1.2 A review of PGE mineralization

Platinum group elements can be classified into two groups according to their different physical and chemical activities and preferred hosts in natural systems (Naldrett, 1999). The two groups are the iridium-group platinum-group elements (IPGEs: Ru, Ir, Os) and the palladium-group platinum-group elements (PPGEs: Pt, Pd, Rh). All these elements are highly siderophile elements, and also behave as

highly chalcophile elements in base metal sulfide (BMS) liquids. Therefore, they are commonly found in association with magmatic BMS deposits, and are hosted by minerals such as chalcopyrite, pentlandite, bornite, pyrrhotite, which crystallized from the sulfide liquid (Barnes and Ripley, 2016).

Magmatic sulfide deposits can be broadly subdivided into two groups according to metal proportions: Ni-Cu deposits with PGE as a by-product and PGE dominant deposit with Ni and Cu as possible by-products (Li et al., 2001). Owing to the different geochemical behaviours of Ni and Cu versus PGE in igneous processes, particularly their different partition coefficients into segregated sulphides and other silicate phases, the formation of these two groups of magmatic sulfide deposits require some different mechanisms. Cu-Ni-(PGE) deposits are rich in sulfide minerals and require a large tonnage of ore to be economic, whereas the PGE-dominant deposits contain much less sulfide minerals (Naldrett, 1999). It is beyond the scope of this review to fully investigate the differences between these two groups of magmatic sulfide deposits, more details can be found in Li et al. (2001), Cawthorn (2005), and Maier et al. (2011). This chapter focuses on PGE-dominant deposits, in particular the geochemistry of PGE, origins of PGE mineralization, types of PGE deposits and their host units.

1.2.1 Geochemical behaviour of PGE elements

The PGE (plus gold) are often called noble elements because the related metals are resistant to corrosion and oxidation in moist air. These elements also tend to be valuable due to their rarity in the Earth's crust, e.g., 0.4 ppb for Pt (Mungall and Naldrett, 2008). PGE are also chalcophile, which means that they are preferentially enriched in sulfide liquids relative to silicate melts. This is particularly true for PPGE which are normally associated with magmatic sulfide minerals of Fe, Ni and Cu, whereas IPGE may also commonly associated with chromite, as native metal alloys or sulfide minerals as shown by experimental work of Capobianco et al. (1994), Righter et al. (2004), and Brenan et al. (2012). The PGE are also transition

elements that have variable valence states, ranging from 0 to +8. Thus, their chemistry is complex, and they can be bonded with various elements to form different kinds of PGM composites, e.g., oxide minerals, sulfide minerals, etc. The PGE (plus gold) have similar and regularly varying chemical characters. For example, the order of decreasing boiling and melting temperatures of these elements is Os, Ir, Ru, Rh, Pt, Pd, and Au (Barnes et al., 1985). This is also the order of decreasing compatibility in magma systems, which is commonly used when plotting chondrite-normalized abundance of PGE elements (plus gold) analogous to rare earth elements, but with the latter ordered by atomic number.

Of particular interest regarding geochemical behaviour of the PGE elements is their partitioning into sulfide liquids. But before illustrating this, it is necessary to describe the evolution of sulfide liquid because different groups of the PGE elements behave differently at different evolutionary stages of the sulfide liquid. Experimental work (e.g., Kullerud et al. 1969; Dutrizac, 1976; Ebel and Naldrett, 1997; Sinyakova and Kosyakov, 2009) has shown that following the segregation of sulfide liquids from a silicate melt at temperatures of around 1200 °C, the first phase to crystallize is an Fe-rich monosulfide solid solution (MSS) at around 1000°C. The remaining sulfide liquid is Cu-rich, which crystallizes intermediate solid solution (ISS) when the temperature drops down significantly (<900 °C). As temperatures drops down to below 650 °C, the MSS recrystallizes to Fe-rich sulfide minerals such as pyrrhotite and pentlandite whereas the ISS recrystallizes to Cu-rich sulfide minerals such as chalcopyrite (Holwell and McDonald, 2010).

Experimental data of Fleet et al. (1993), Li et al. (1996), Barnes et al. (1997), Mungall et al. (2005), Liu and Brenan (2015), and Brenan et al. (2016) suggest that in sulfur-rich, alloy-poor systems the IPGE and Rh partition into MSS, whereas Pt and Pd will partition into Cu-rich residual liquids after MSS crystallization. Liu and Brenan (2015) suggest that there is a significant effect of oxygen on increasing the activity for IPGE and Rh partitioning into MSS. As a result, IPGE and Rh elements

are preferentially hosted by phases that crystallized from MSS such as pyrrhotite and pentlandite. But for Pt and Pd elements, experimental results of Peregoedova (1998) suggested that they were incompatible with ISS, thus the crystallization phases of ISS such as chalcopyrite would not be favorable hosts to these two elements. Barnes and Ripley (2016) compared PGE contents of the base metal sulfide minerals such as pyrrhotite, pentlandite, chalcopyrite, and pyrite, and found that pentlandite has the highest PGE and the concentrations of all of the PGE are low in chalcopyrite. Rather, work by Helmy et al. (2007) suggested that the Cu-rich residual melt remained liquid after ISS had crystallized, which was transformed into an immiscible semimetal-rich melt where Pd and Pt were concentrated. The semimetal-rich liquid may be enriched in Te, Bi, As, and Sb, thus Pt and Pd are easily combined with these elements to form discrete platinum group minerals (PGM) after the crystallization of the semimetal-rich sulfide liquid. However, it should be noted that at high Pd: semimetal ratios, some excess Pd can not be accommodated by the semimetal-rich sulfide liquid and may partition into MSS (Helmy et al., 2007). This explains the presence of Pd in pentlandite in some ores. However, the mechanism and temperature controls on this are still poorly understood. Nevertheless, the semimetals appear to be the most fundamental factor controlling the mineralogical characteristics of magmatic sulfide-hosted Pt and Pd ores. Barnes and Ripley (2016) suggested that since the major elements of magmatic sulfides have been consumed there is very little semimetal-rich sulfide liquid remaining, thus Pd and Pt may end up being enriched in the ISS cumulate (Cu-rich ore). The schematic cartoon of the partition of PGE elements into different stages of magmatic sulfide liquids is shown in Figure 1-2.

Figure 1-2. Schematic cartoon of a fractionating, platinum group element-rich sulfide droplet, see text for full interpretation, modified after Holwell and McDonald (2010).

1.2.2 Origin of PGE mineralization

Two main genetic models for PGE deposits have been proposed: primary magmatic (also known as orthomagmatic) or concentration of PGE by late fluids. The former model is favored by most authors, who interpret that PGE deposits as having formed by high temperature magmatic processes in mafic-ultramafic igneous rocks, whereas the late fluids are interpreted to be relatively minor significant in terms of PGE mineralization (Naldrett et al., 2008; Maier, 2005).

There are at least three requirements for formation of PGE ores by the primary magmatic sulfide model. The first requirement is for the PGE fertile magma. Although there are several ways in which PGE fertile magmas may be generated, the most generally accepted way that is proposed to be applicable to most known PGE deposits is formation of intraplate picritic magmas from a high degree of partial melting of the mantle (Arndt et al, 2005; Barnes and Lightfoot, 2005). This is because sulfide minerals probably are the main host to PGE elements in the mantle

(see Barnes and Maier, 1999, and references therein) owing to the high partition coefficients of PGE into sulfide liquids (~ 10000 for Pd and Pt, Barnes and Maier, 1999), and only large degrees of mantle melting, e.g., $\sim 25\%$ depending on the depth of melting, is ready to dissolve all the sulfides in their mantle source regions (Maier, 2005). However, Botcharnikov et al. (2011) suggest that at least gold-rich magmas can be generated in mantle systems that are sulfide-saturated, as long as they are relatively oxidized.

The next requirement is the saturation of sulfide melt in a fertile magma, which occurs after the magma has ascended to the upper crust. The early sulfide segregation prior to the ascent of PGE fertile magma will inevitably deplete the remaining magma in PGE, thus is considered not favorable for formation of PGE deposits. However, it should be noted that some studies (e.g., Blaine et al., 2011) suggest that it is possible that Pt metal saturation may occur before sulfide saturation if the melt exsolves a chlorine-rich fluid. Once sulfide melt saturation occurred when the magma has emplaced in the crust, PGE elements can be concentrated in the immiscible sulfide melt to form economic ores.

Following the work of Fincham and Richardson (1954) who discussed the solution of S in silicate melts in terms of reaction between base metal oxides and either S^{2-} or SO_4^{2-} , several well-constrained experimental studies have been undertaken to investigate the solubility of sulfur (S^{2-} or SO_4^{2-}) in the magma. When sulfur is present as S^{2-} in the magma, i.e., sulfide liquid, Shima and Naldrett (1995) have referred to this value as the S content at sulfide saturation, which is known as SCSS. Generally, there are four mechanisms that can provoke the sulfide melt saturation. The first mechanism is a large degree of magma fractionation. Since sulfide does enter any silicate phases, during fractionation the concentration of sulfide will progressively increase until reaching SCSS (Mungall and Naldrett, 2008). The second mechanism is the decrease in FeO contents by fractionation of Fe-rich minerals such as olivine, pyroxene, and magnetite. This will reduce the capacity for

the magma to carry dissolved sulfide (Haughton et al., 1974; Li and Ripley, 2005), which in turn triggers the sulfide saturation. The third mechanism is the contamination of the magma by sulfidic country rocks (Ripley, 1999; Leshner and Campbell, 1993). This process is believed to be a very feasible way to provoke sulfide saturation because: 1) country rocks may contain a high amount of sulfur, through the contamination extra S is introduced in the magma, thus triggering the sulfide saturation, 2) the contamination may introduce silica into the magma, decrease the temperature of magma, and increase oxygen fugacity of the magma, all of these will lower the SCSS of the magma (see Li and Naldrett, 1993; Li and Ripley, 2005), 3) the increasing oxygen fugacity by contamination may in turn lead to the fractionation of magnetite and lowering of the FeO content and thus the SCSS of the magma (Li and Ripley, 2005). It is, however, should be noted that this contamination process normally triggers the immiscibility of large amounts of sulfide melts, which is more applicable to formation of Cu-Ni-(PGE) deposits such as Noril'sk of Siberia in Russia and Jinchuan in China (Naldrett, 1997). By contrast, the formation of PGE deposits by such means requires a delicate balance to achieve the right amount (normally a small amount) of excess sulfide in the resulting mixture (Mungall and Naldrett, 2008), thus this process is not favorable for formation of PGE deposits because large amounts of sulfide liquid mean the R-factor (weight fraction of silicate melt/ weight fraction of sulfide liquid) would be small, leading to low PGE concentrations in sulfide liquids. The fourth mechanism is the mixing of compositionally contrasting, sulfur undersaturated magmas. This is illustrated by the work of Li et al. (2001) and Cawthorn (2002) who suggested that mixing of a siliceous melt and a liquid of olivine tholeiite composition can provoke sulfide liquids saturation.

Once the magma became sulfur saturation and immiscible sulfide liquids have formed by mechanisms mentioned above, they must be collected and concentrated in order to produce an economic ore deposit that can be mined, which is the third

requirement for formation of PGE deposits. Normally, the dense sulfide melt droplets segregate to the base of the magma chamber and crystallize to form a sulfide minerals- enriched zone where the highly chalcophile PGE are concentrated. If the immiscible sulfide droplets formed from the magma flowing in a conduit, they may be suspended in the melt, particularly when there is no change in the flowing regime, e.g., the widening of the conduit (Mungall and Naldrett, 2008). The suspended sulfide droplets may react with the later pulses of sulfur undersaturated magma intrusions, and may undergo a ‘sulfide dissolution upgrading’ process where the PGE tenor of sulfides is progressively upgraded. This process has been successfully modelled by Kerr and Leitch (2005).

There are also numerous studies favoring a role of hydrothermal fluids on PGE mineralization, e.g., hydrothermal veins at Kambalda (Leshner and Keays, 1984), Stillwater J-M reef within the Stillwater Complex in the USA (Boudreau et al., 1986), Sudbury footwall ores at Canada (Farrow and Watkinson, 1999), the Marathon deposit of the Coldwell Alkaline Complex at Canada (Watkinson and Jones, 1996), and footwall ore of Duluth Complex at USA (Benko et al., 2015). Experimental studies of Hsu et al. (1991), Fleet and Wu (1993), and Baker et al. (2001) confirmed that Pd and Pt are highly soluble in chlorine-rich fluids. Blaine et al. (2011) experimentally determined the effect of chlorine on Pt solubility in haplobasaltic melt and found that chlorine-rich fluids can be highly efficient at enriching and transporting Pt in mafic magmatic-hydrothermal ore-forming systems at moderate oxygen fugacities. Hanley et al. (2005) investigated the solubility of platinum and gold in NaCl brines at 1.5 kar and 600-800°C, and proposed that the solubility would be enhanced with increasing fluid salinity. In addition, some studies also suggest that Pt and Pd sulfide minerals are also soluble in aqueous H₂S-rich fluids, but to a lower extent than in chlorine-rich fluids. For example, Pan and Wood (1994) experimentally determined solubility of Pd and Pt sulfide minerals in H₂S-rich aqueous fluids (200-350°C) to be 4-800 ppb for Pt and 1-400 ppb for Pd.

Gammons and Bloom (1993) suggested that the solubility of Pd and Pt sulfide minerals in H₂S-rich aqueous fluids increase with increase in $\sum S^{2-}$ and decrease with increase in temperature particularly between 200 and 300°C.

In this regard, it is plausible that the fluids partially dissolve BMS, and as a consequence, Pd and Pt dissolve into the fluid, which finally precipitated when the physico-chemical conditions change (Barnes and Ripley, 2016). Such a process has been proposed by Mathez (1995) to explain the enrichment of PGE of Merensky Reef pyroxenites at the Bushveld Complex in South Africa, and also is adopted to explain the occurrences of PGE mineralization in faults and shear zones associated with the mafic-ultramafic intrusions (Maier, 2005). In some cases, fluids derived from cooling or metamorphism may result in a change of mineralogy of BMS and PGM. For example, Djon and Barnes (2012) found that pyrrhotite and pentlandite at Lac des Iles in Ontario of Canada were replaced by pyrite and millerite under the influence of fluids, and as a consequence the pyrite was enriched in IPGE and Rh that were initially present in pyrrhotite. Hutchinson and Kinnaird (2005) found that at Platinova reef within the Skaergaard intrusion of Greenland, the PGM assemblage in the altered ores is enriched in arsenic and antimony. Although the evidence for the hydrothermal fluids-related controls on PGE mineralization is well documented by some studies, many researchers have voiced scepticism whether this mechanism could be responsible for formation of most deposits, and many believed the role of hydrothermal fluids on PGE mineralization is only of minor significance for most deposits (e.g., Maier and Barnes, 1999).

There are also some studies proposing a vapor refinement model (also called hydromagmatic model) for the formation of Pt deposits, e.g., the J-M reef of the Stillwater Complex at USA (Boudreau and Meurer, 1999; Boudreau, 2016), Lower and Critical Zones of the Bushveld Complex at South Africa (Willmore et al., 2000), and the Marathon Cu-Pd deposit of the Coldwell Alkaline Complex at Canada (Dahl et al., 2001; Barrie et al., 2002; Samson et al., 2008). In this model, mineralization

is introduced by the interaction between chlorine-rich fluid and silicate melt, e.g., the upward migrating chlorine-rich fluid re-dissolves into the volatile-undersaturated melt. Blaine et al. (2011) suggest that this process possibly would lead to the formation of PGE-bearing phases (e.g., micronuggets) and could allow the bulk PGE content of the magma to increase above the limits imposed by the PGE solubility.

1.2.3 Classification of PGE deposits

The majority of the world's PGE ore deposits are magmatic in origin and occur within mafic and ultramafic portions of large tholeiitic intrusions of late Archean to early Proterozoic age (Maier, 2005). As mentioned earlier, the PGE deposits can be first subdivided into two main types according to whether Ni, Cu, versus PGE are the main economic commodities, they are Ni-Cu-(PGE) deposits and PGE-dominant deposits. More detailed classification of Ni-Cu-(PGE) deposits are proposed by Sutphin and Page (1986), Keays and Lightfoot (2002), Naldrett (2004), and Eckstrand and Hulbert (2007). This chapter only focuses on PGE-dominant deposits. There are two principle subtypes of magmatic PGE-dominant deposits: stratiform or reef deposit and contact deposits (Eckstrand and Hulbert, 2007; Barnes and Ripley, 2016). In addition, depending on the relative roles of magmatism and fluids on PGE mineralization, another type of PGE deposit is late magmatic and/or hydrothermal fluid related (Maier, 2005).

The stratiform or reef type deposits occur in the well layered mafic/ultramafic intrusions, and their ore bodies take the form of laterally extensive layers. Examples of this type of deposits include the UG2 and the Merensky reef of the Bushveld Complex in South Africa, J-M reef of the Stillwater Complex of the USA, and the Main Sulfide Zone of the Great Dyke at Zimbabwe. Various mafic to ultramafic host rocks are generally present for reefs at these different settings. For example, the UG2 reef is hosted by massive chromitite with interstitial orthopyroxene and plagioclase (Barnes and Maier, 2002), the Merensky reef is hosted by rock types

ranging from chromitite, through melanorite, to anorthosite (Barnes and Maier, 2002), the J-M reef is hosted mainly by troctolite, olivine gabbro-norite and anorthosite (Barnes and Naldrett, 1985), and host rocks for the Main Sulfide Zone comprise orthopyroxenite or bronzitite (Wilson and Brown, 2005).

The contact-type deposits (also called magmatic breccia type in Eckstrand and Hulbert, 2007) refer to those with ore bodies in variable width. The ore bodies are located at the margins of intrusions, and are in the form of disseminated BMS. Examples of this type of deposits include the Platreef of the Bushveld Complex in South Africa and Lac des Iles deposit in Canada. Note that Platreef, although termed a reef type deposit, essentially belongs to the contact type because it is a relatively wide zone (50-100 m thick) with variable distribution of PGE across the zone (Barnes and Ripley, 2016). Host units of this type deposits vary from pyroxenite to gabbro-norite, with minor anorthosite and peridotite (Maier et al., 2008; McDonald and Holwell, 2011).

1.3 Geology of the Coldwell Alkaline Complex

The Coldwell Alkaline Complex is the largest alkaline intrusion in North America. It is associated with the North American Midcontinent Rift (Fig. 1-3) and is one of the largest known intrusions associated with continental rifts in the world (Heaman and Machado, 1992). It intruded the Archean Shreiber-Hemlo greenstone belt along the northern edge of the Midcontinent rift at 1108-1094 Ma, which marked the beginning of the early stage of magmatism related to the Midcontinent rift system (Walker et al., 1993; Heaman et al., 2007; Good et al., 2015). Petrologic and field studies conducted by Puskas (1970), Mitchell and Platt (1978, 1982), Mitchell et al. (1993), and Shaw (1997) recognized three superimposed intrusive centers constituting this complex, from east to west, they are center I, center II, and center III (Fig. 1-4). Center I is composed of syenite, syenodiorite, layered ferroaugite-amphibole syenite, and an outer rim of complicated gabbroic and ultramafic rock units known as the Eastern Gabbro (Fig. 1-4). Most PGE mineralization at the

Coldwell Alkaline Complex is hosted by the Eastern Gabbro. Center II comprises nepheline-bearing alkali biotite gabbro, hastingsite-bearing miaskitic nepheline syenite, and minor lamprophyres and tinguaitite dikes. Center III consists of magnesio-hornblendesyenite, ferro-edenite syenite, quartz syenite, and minor granites (Mitchell and Platt, 1978; Mitchell et al., 1991). Paleomagnetic work conducted by Ashley and Kerns (2012) suggests that Centers I and III are the same age but both are older than Center II. It was proposed by Mitchell and Platt (1977, 1978) and Walker et al. (1993) that the emplacement of most rock units in the Coldwell Alkaline Complex was controlled by the faulting during cauldron subsidence at a subvolcanic depth.

The Eastern Gabbro formed by multiple intrusions of basaltic magma with a subalkaline parentage into a partial ring dike structure that cut the Archean country rocks (Shaw, 1994, 1997). Good et al. (2015) identified nine major lithologies that are temporally related through crosscutting relationships. These nine lithologies can be categorized into three major distinctive Magmatic Series by their geochemical character, e.g., different Nb/Zr and Ce/Y ratios (Good et al., 2015). From oldest to youngest, the three magmatic series includes: the meta-basalt (equivalent to fine-grained gabbro in Good et al., 2015), the Layered Series, and the Marathon Series. The relative ages for these units were established from crosscutting relationships, particularly within the numerous units of igneous breccia (Good et al., 2015).

The meta-basalt occurs along the base of the Eastern Gabbro and comprises picritic basalt that underwent pyroxene-hornfels grade metamorphism (Good et al., 2015). It was crosscut by both the Layered Series and the Marathon Series as observed by Good et al. (2015) at the Marathon deposit. The Layered Series constitutes the bulk of the Eastern gabbro and is composed of massive to modally layered olivine gabbro, with a lesser amount of weakly layered oxide augite melatroctolite, and, less commonly, gabbroic anorthosite. Based on drill core logging, the Layered Series at Area 41, Four Dams, and the WD zone (locations are indicated in Fig. 1-4) was

crosscut by numerous thin Marathon Series intrusions. The Marathon Series is the youngest unit and comprises numerous small intrusions composed predominantly of ophitic gabbro, apatitic clinopyroxenite, oxide melatroctolite, as well as small volumes of augite troctolite and wehrlite (Good et al., 2015). Based on compositions and similar textures, the Marathon Series at Area 41, Four Dams, and the WD zone is similar to that at the Marathon deposit. It should be noted that at the Marathon deposit, the most significant Marathon Series rock is the Two Duck Lake gabbro, which is the main host to Cu-Pd mineralization at this deposit (Good et al., 2015). The Two Duck Lake gabbro has an ophitic texture and resembles the ophitic gabbro at Area 41, Four Dams, and the WD zone in terms of textures and geochemical characters (full details will be shown in Chapter 6).

1.4 PGE deposits at the Coldwell Alkaline Complex

There are various mafic to ultramafic Ni-Cu-PGE deposits associated at the margins of the Midcontinent Rift. Most of them contain disseminated-massive sulfide mineralization found within sheet-like gabbro to troctolite intrusions, or are associated with conduit-related smaller, early rift, mafic to ultramafic intrusions (Ripley, 2014). For example, the Partridge River and South Kawishiwi of the Duluth Complex (Ripley, 2014) are sheet-like intrusions that host the basal contact-type Cu-Ni-PGE mineralization. Current Lake deposit (Goodgame et al., 2010), the Eagle deposit (Schulz et al., 2010; Ding et al., 2012), and the Tamarack occurrence (Goldner, 2011) are the Ni-Cu-PGE conduit style mineralization. The Locations of these notable deposits are indicated on Figure 1-3. Another type of PGE-related deposit associated with the Midcontinent Rift is relatively low sulfide and PGE enrichment found as stratiform intervals in well-differentiated tholeiitic layered intrusions (Ripley, 2014). This type of deposits is volumetrically small within the Midcontinent rift system, and some are concentrated within the Coldwell Alkaline Complex, notably the Geordie Lake Cu-PGE deposit and the Marathon Cu-Pd deposit (Fig. 1-4). These two deposits will be reviewed in order to provide

geological context for mineralization at Area 41 (location is indicated in Fig. 1-4), which will be examined in chapter 5.

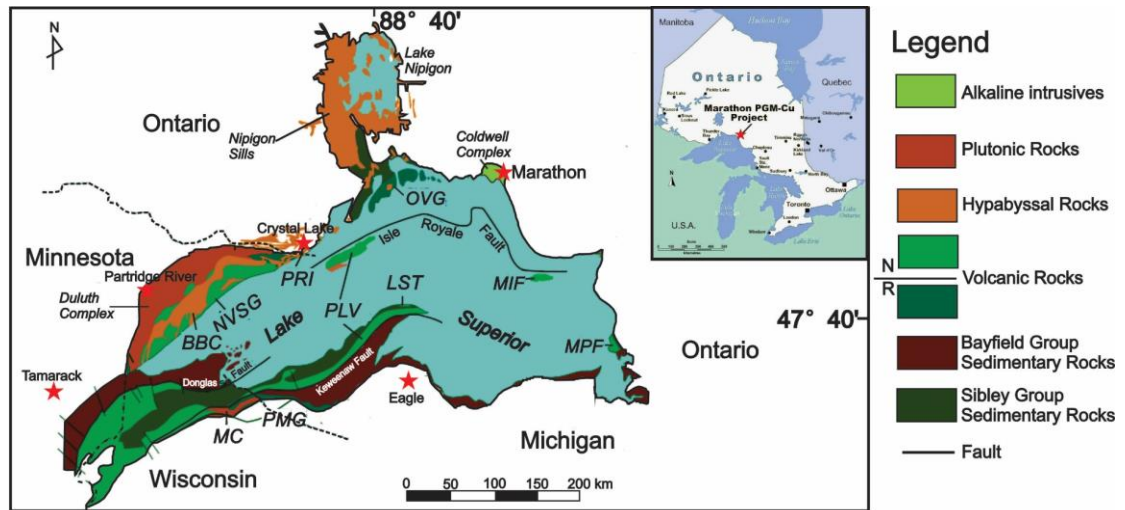

Figure 1-3. Regional map of the Midcontinent rift (modified after Miller and Nicholson, 2013). *BBC* Beaver Bay Complex, *NVSG* North Shore Volcanic Group, *PRI* Pigeon River Intrusion, *OVG* Osler Group, *MPF* Mamainse Point Formation, *MIF* Michipicoten Island Formation, *PLV* Portage Lake Volcanics, *LST* Lake Shore traps, *PMG* Powder Mill Group, *MC* Mellen Intrusive Complex. Notable deposits are indicated using red stars.

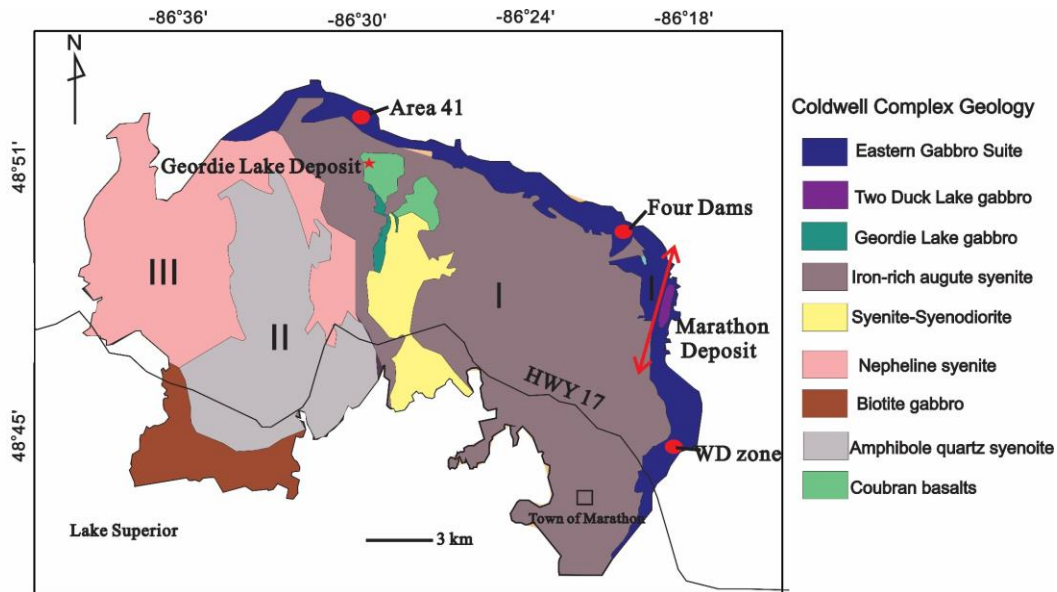

Figure 1-4. Geological map of the Coldwell Alkaline Complex, situated on the northern shore of Lake Superior. Locations of Area 41, Four Dams, and WD zone (these three areas are involved in this thesis study) are represented as three red dots. Locations of the Georgie Lake deposit and Marathon deposit are also indicated using a red star and a double-headed red line, respectively (Modified after Walker et al., 1993). The intrusive centers have been shown by Roman numerals (modified after Mulja and Mitchell, 1991).

1.4.1 Geordie Lake Cu-Pd deposit

The Geordie Lake gabbros and troctolites are small mafic, weakly layered, and elongate intrusions located in the central part of the Coldwell Alkaline Complex (Fig. 3). Mineralization in the Geordie Lake intrusion was discovered in 1960 when Ameranium Inc. explored for copper at this area. The subsequent drilling and exploration programs conducted by St. Joe Canada Inc, Gryphon Metals Corporation, Discovery PGM, Marathon PGM. The first resource estimate for the Geordie Lake Deposit by Discovery PGM was 24.4 million tonnes averaging 0.326 % Cu, 0.537 g/t Pd, 0.007 % Co, 0.011 % Ni, 0.030 g/t Pt, 2.52 g/t Ag and 0.04 g/t Au. An additional 5.4 million tonnes are considered inferred at an average grade of 0.36%Cu, 0.626 g/t Pd, 0.007% Co, 0.012% Ni, 0.04 g/t Pt, 3.04 g/t Ag and 0.05 g/t Au (Drennan and Fell, 2010).

Two types of gabbros were recognized at Geordie Lake by Good and Crocket (1994) and Meghji (2016): homogeneous and heterogeneous types, with only the latter contains abundant sulfide and Pd mineralization. Mulja and Mitchell (1991) also studied the petrography of sulfides and PGM at the Geordie Lake intrusion. Sulfide minerals within the Geordie Lake intrusion principally are disseminated chalcopyrite, with less amounts of bornite, pyrite, millerite, cobaltite, sphalerite, and galena. The PGM are dominantly palladium tellurides and arsenides, with rare Pt-PGM such as sperrylite.

Mulja and Mitchell (1991) found that tellurides and PGM were associated primarily with disseminated magmatic chalcopyrite, with rare cases in late-stage massive chalcopyrite. However, Good and Crocket (1994) found that disseminate sulfides and palladium minerals were spatially in close association with albite pods that they interpreted to represent pockets of fluid-rich residual magma. These different observations led to two different emplacement models proposed by the two studies. Mulja and Mitchell (1991) favored a magmatic origin for the Cu-PGE mineralization at the Geordie Lake deposit. They suggested that the mineralization

was associated with the segregation of a relatively evolved sulfide melt from an evolved tholeiitic magma. Factors that induced the sulfide melt segregation include the rapid cooling of the magma and the crystallization of olivine and magnetite. The crystallization of Ti-poor magnetite, tellurides, and PGM from the sulfide melt occurred at <550°C.

On the other hand, Good and Crocket (1994) found that the albite pods had higher abundances of Zr, Hf, Nb, Th, U, and the rare earth elements (REE) than the surrounding Geordie Lake gabbro, but inter-element ratios are similar between the two rock types. They interpreted the albite pods to be representative of pockets of fluid-enriched residual magma, and formed by a two-stage process, including the crystallization of hornblende and plagioclase from the residual magma (stage one) and a hydrous fluid separated from the residual magma and interacted with the plagioclase to form the albite (stage two). The close association of PGM and sulfides with the albite pods thus implies that the PGE mineralization formed from the same fluid with the albite pods, but at different times when the fluid underwent evolution and cooling processes.

Meghji (2016) recently examined the structure and control of Cu-PGE mineralization at the Geordie Lake deposit, and explored how the distribution of Cu-PGE mineralization varied by host lithology, and by various degrees of secondary alteration. He found that the Cu-PGE mineralization at the Geordie Lake deposit was spatially in close association with gabbro and troctolite that present weak to intense actinolite and albite alteration. The similar major element geochemistry between the altered and unaltered samples led Meghji (2016) to propose that sulfide deposition at the Geordie Lake deposit is magmatic, and the interaction with late stage magmatic fluid redistributed some mineralization.

1.4.2 Marathon Cu-Pd deposit

The Marathon Cu-Pd deposit is the largest deposit within the Coldwell Alkaline Complex. It is located approximately at the middle part of the Eastern Gabbro; the

Eastern Gabbro forms the Eastern margin of the Complex (Fig. 4). It is a PGE-relatively rich & sulfide-poor deposit (Ruthart, 2013). The initial exploration of the Marathon deposit was for a large Cu deposit by Anaconda in 1963. Since then, the property has changed hands several times and is currently owned by Stillwater Canada Inc. The latest estimate of the size and grade of the Marathon deposit resource (in-pit, measured plus indicated) are 97.4 million metric tons (Mt) at 0.27% Cu, 0.75 ppm Pd, 0.23 ppm Pt, and 0.09 ppm Au (Puritch et al., 2009).

The major mineralization zones at the Marathon deposit have been divided into Four Zones: the Main Zone, the Footwall Zone, the Hanging Fall Zone, and the W-Horizon. The mineralization of these four zones is mainly hosted by the Two Duck Lake gabbro, with lesser amounts hosted by an apatitic clinopyroxenite and oxide melatroctolite. All of these units belong to the Marathon Series. Sulfide minerals in the Main Zone, the Footwall Zone, the Hanging Fall Zone consist of disseminated chalcopyrite, pyrrhotite, and minor amounts of cubanite, bornite, pentlandite, cobaltite, and pyrite (Good et al., 2015). Only trace amounts of sulfide minerals occur within the mineralized Two Duck Lake gabbro at the W-Horizon, but where sulfide minerals are present they are mainly chalcopyrite and bornite, with minor pyrrhotite and trace amounts of pentlandite and pyrite (Ruthart, 2013).

Approximately 70% of mineral resource is contained within the Main Zone (Good et al., 2015). The Main Zone and the W-Horizon are of the particular interest because they are located at the north and south ends, respectively, of the Two Duck Lake Intrusion and exhibit notably different Cu/Pd ratios (Good et al., 2015). The Main Zone has Cu/Pd ratios typically within 1000-10000 (mantle range; Good et al., 2015), whereas the W-Horizon is characterized by an extremely enrichment of Pd plus Pt relative to Cu and has $\text{Cu/Pd} < 1000$ (Ruthart, 2013). In addition, the Main Zone and W-Horizon also differs in terms of PGM hosts and assemblages. Puritch et al. (2009) reported details of the platinum group minerals within the Main Zone and W-Horizon Zone of Marathon Cu-Pd deposit, and found that within the Main

Zone the PGM are dominantly kotulskite-sobolevskite solid solution, hosted by sulfide minerals > hydrous silicate minerals > within plagioclase boundaries whereas within W-Horizon Zone the PGM are dominantly zvyagintsevite-palladinite, hosted by sulfide minerals > plagioclase boundaries > other PGMs > hydrous silicate minerals.

Numerous studies have examined the genesis of the Marathon Cu-Pd deposit and three general models have been proposed to explain the PGE mineralization at this deposit. The first model proposes a hydrothermal origin for mineralization (e.g., Ohnenstetter et al., 1991, Watkinson and Ohnenstetter, 1992, Watkinson and Jones, 1996, Dahl et al. 2001, Barrie et al., 2002, and Brzozowski et al., 2015). In this model, Cu and PGE were initially concentrated by magmatic processes and were remobilized by Cl-rich fluids from the lower parts of the deposit to higher levels when they are deposited. The model explains the commonly observed association of Cu-rich sulfide minerals and PGM with secondary hydrous mineral assemblages, pegmatitic rocks, and Cl-rich minerals in the Main Zone. Another model is related to the zone refining (Dahl et al., 2001; Barrie et al., 2002; Samson et al., 2008). In this model, magmatic sulfides were modified by fluid-rock interaction.

The last and perhaps the most applicable model is related to magmatism, proposed by Good and Crocket (1994) and Good et al. (2015) for sulfide minerals at the Main Zone, and by Ruthart (2013) for mineralization at the W-Horizon. In this model, the Cu-PGE mineralization was mainly controlled by sulfide liquid segregation from the silicate melt, and the compositions of sulfides are governed by partition coefficients of Cu and Pd between silicate melt and sulfide liquid, and by the silicate melt to sulfide liquid ratio (R-factor) (Good et al., 2015). The extreme enrichment of PGE in the W-Horizon was interpreted by Ruthart (2013) to be the result of magmatic ‘multistage dissolution upgrading’ process, similar to the mechanism proposed by Kerr and Leitch (2005).

Barrier et al. (2002) and Miller and Nicholson (2013) defined the Marathon deposit as a contact-type deposit because many of the deposit characteristics match those described for contact-type occurrences. For example, the grades for the Marathon deposit (0.27% Cu, 0.75 g/t Pd, 0.23 g/t Pt, and 0.09 g/t Au) closely match the median values for a total of 37 contact-type ore deposits (0.25%, 0.62, 0.245, and 0.0846 g/t, respectively) as determined by Zientek (2012). By contrast, Good et al., (2015) proposed that this deposit more reasonably belonged to the conduit-type deposits based on: 1) the high proportion of sulfide minerals relative to the host rocks, an important factor in defining conduit systems (Maier et al., 2001), 2) an extrusive volcanic equivalent of the Two Duck Lake Intrusion (the Coubran basalts) is consistent with conduit setting, 3) the shape of the Two Duck Lake gabbro resembles a chonolith rather than a sill-like intrusion, 4) petrological evidence (the replacement of early plagioclase by later more calcic plagioclase) that the Two Duck Lake gabbro formed by multiple intrusions, and, 5) identification of magma pathways along the footwall contact of the Two Duck Lake intrusion.

Chapter 2

Methodology

2.1 Sample preparation

2.1.1 Powders

Powdered samples were collected by grinding 1 m-long channels along the drill core approximately 2 mm wide and 1 cm deep using a Thermo Scientific portable grinder (Fig. 2-1 A & B). A typical sample required 2 to 5 minutes to collect and produced ca. 10 to 200 μm of powder. Seven pXRF analyses were made on powders that were re-ground using a mortar and pestle, which were compared to pXRF analyses conducted on the original powders (before re-ground) in order to evaluate the influence from grain size. Results are tabulated in Table 2-1 and compared in Figure 2-2. It shows that the re-ground had little effect on the results.

Samples were taken at intervals of ca. 4.5 m along the length of the drill hole. Cross-contamination was minimized by washing the collection vial, cleaning off the grinder blade, pre-contaminating the vial by grinding some of the sample, shaking the vial to coat the vial with the sample dust and dumping out the vial, and then collecting the powdered sample to be analyzed. All powders were then loaded into PREM-4331 XRF sample cups (powders were packed by hand when they were in cups) capped with 4- μm PREM-F2540 XRF sample cup films for the pXRF analysis (Fig. 2-3).

Figure 2-1. Pictures showing the appearance of the drill core after grinding. (A) Drill cores in the box, note the two parallel channels along the length of the top drill core after cutting the core for powders collection; (B) The portable grinder used to cut drill cores for collecting powders.

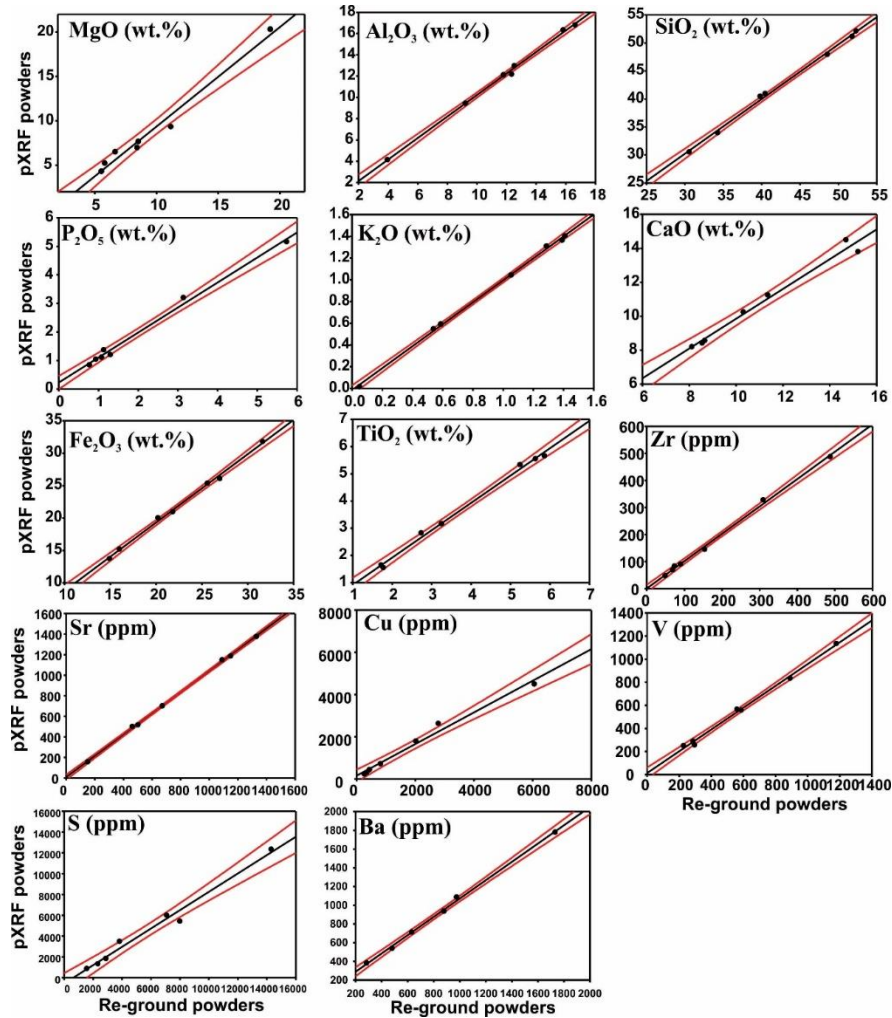

Figure 2-2. The comparison of pXRF whole-rock results determined on powders before and after re-ground. The black line indicates the regression line and the red lines in each diagram represents the 95% confidence interval.

Figure 2-3. Powders in cups that are ready for pXRF analysis.

The potential for contamination of Fe, Cr and Ni by the grinder blade was tested by sampling a piece of pure quartz (Fig. 2-4). The pXRF analyses are presented in Table 2-2 and show that grinder blade-related contamination for most elements except Ni is insignificant, with less than 0.1 wt. % for most major elements and lower than the detection limit for trace elements. Approximately 100 ppm of Ni is added to each sample during grinding. A subset of representative powdered samples was further pulverized for laboratory-based whole-rock analyses.

LOD, limit of detection

2.1.2 Rock specimens

Drill core samples that are representative of different series' gabbro units with different styles of mineralization (e.g., chalcopyrite-rich, and pyrrhotite-rich) were collected down selected drill holes, with an interval of 5 to 20 meters between every two core samples. Each core sample is about 10 cm in length. After taking pictures and describing the lithology of core samples, thin section blocks were made through cutting core samples using a diamond saw. A subset of thin section blocks was analyzed by bSEM-EDS in order to test the field portability of this analytical equipment. All thin section blocks were then made into thin sections for petrographic and mineral chemical analyses.

2.2 Analytical equipment

2.2.1 pXRF analysis

A Niton XL3t+ GOLDD+ pXRF analyser equipped with a solid drift detector (SDD), and a high energy, 50kV X-ray Ag anode tube was used in this study. All pXRF measurements were carried out on powders after calibrating the pXRF analyser using a suite of matrix-matched standards, including two U.S. Geological Survey reference materials, BHVO-2 basalt and W-2a diabase, and seven Marathon gabbro internal standards. This suite of standards covers a wide range of concentrations for elements measured in the current work: SiO₂, Al₂O₃, CaO, Fe₂O₃ (as total Fe), TiO₂, K₂O, P₂O₅, MgO, Ba, V, Zr, Sr, Cu, and S. Major elements were determined using the instrument's 'mining mode', with two beams, whereas minor and trace elements were determined using the 'soil mode', with three beams; beam time for both modes

was 60 s. The QA/QC control throughout all analyses was carried out by analyzing two standards after each batch of unknown samples (20 samples typically). A blank standard (98.2 wt. % SiO₂) was analyzed at the beginning and the end of each batch measurement to monitor cross-contamination from the test stand and check for machine drift. Typically, a new calibration was conducted after every two batches of unknown samples. The intent was to acquire the highest quality of results and less-frequent calibration may have yielded a similar result. The analytical error for pXRF analysis with 95% confidence (2σ) was determined through duplicate analyses conducted on the same sample.

2.2.2 Conventional whole-rock analysis

Conventional whole-rock chemical analyses were carried out by ALS Mineral Divisions in Vancouver and Thunder Bay on powders that were initially analyzed by pXRF. Both labs use the same methods for analyzing various elements. After further pulverization, Major elements were analyzed by lithium borate fusion with inductively coupled plasma (ICP)-atomic emission spectroscopy (AES) on a minimum 2 g of pulp samples. Trace elements were analyzed by lithium borate fusion and ICP-mass spectroscopy (MS) on 2 g of sample. Total S was analyzed using a Leco furnace on 1 g of sample. Ferrous Fe was analyzed by H₂SO₄-HF acid digestion and titration on 1 g of sample. Quality-control was conducted based on ALS Chemex quality-control procedures which involve analyses on a wide array of standards, blanks, and duplicates after each batch of samples. The analytical error for conventional whole-rock analysis with 95% confidence (2σ) was determined through duplicate analyses conducted on the same sample. In addition, two different data sets were also prepared, including Stillwater Canada Inc. exploration assays of Cu, S, Ni, Au, Pt, Pd down all included drill holes and 8 high precision S, Se, Pt, Pd, Au, Os, Ru, Ir, and Rh analyses down the PGE-enriched horizon in SL-13-36 (see Chapter 6). The exploration assay data were determined on continuous 2 m sample intervals, and the other data set was collected from eight 2-m-thick, high-grade PGE

intervals at drill hole SL-13-36. Both data sets were analyzed at ALS Thunder, Ontario, by fire assay and mass spectrometer finish (FAMS).

2.2.3 Benchtop SEM-EDS analysis

Major constituents of plagioclase, clinopyroxene, and olivine were determined using a JEOL JMC-600 NeoScope SEM equipped with a JEOL JED-2300 energy dispersive X-ray analyser at Western University. Analyses were conducted using 15 kV accelerating voltage, a high probe current, a working distance of 19 mm, and 30 to 40 μm beam size with standardless ZAF corrections. Unpolished thin section blocks were analyzed under low vacuum mode and carbon-coated polished thin sections were analyzed under high vacuum mode. The analytical precision of bSEM-EDS analyses has been determined by analyzing the same spot 10 times: results are ± 0.51 for Mg# of olivine, ± 1.0 for Mg# of clinopyroxene, and ± 0.63 for anorthite content of plagioclase (1σ standard deviation). The analytical precision (machine error), combining with the nature variation, constitute the sample variability determined through bSEM-EDS analyses on 3-5 grains of each mineral type in each sample.

2.2.4 Electron microprobe analysis

Major and minor constituents of olivine, clinopyroxene, plagioclase, alkali feldspar, and biotite were analyzed using an accelerating voltage of 15 keV and a beam current of 20 nA. The beam was focused to a 1 μm spot for analyzing olivine and clinopyroxene, and to a 5 μm spot for analyzing plagioclase, alkali feldspar, and biotite. The peak counting time was 30 s for all elements and background counts were a total of 30 s. A variety of synthetic and natural standards were used to calibrate different elements during probe analyses. The precision of electron microprobe analyses was determined to be ± 0.07 for Mg# of olivine, ± 0.30 for Mg# of clinopyroxene, and ± 0.15 for plagioclase anorthite content (1σ standard deviation), determined by analysis of the same spot 10 times.

Chapter 3

The application of portable XRF and benchtop SEM-EDS to Cu-Pd exploration in the Coldwell Alkaline Complex, Ontario, Canada

3.1 Introduction

Diamond drilling is arguably one of the most important techniques in mineral exploration, and the geochemical analysis of drill core is an essential component of any diamond drilling program. Conventional laboratory geochemical analyses have high accuracy and precision, however, time delays in obtaining results mean that lab-based measurements are not well suited for making rapid decisions in the field. A number of field-portable analytical techniques are designed to collect data with minimal time delay and at low cost. Thus, the mineral exploration industry is increasingly using field portable instruments in modern mineral-exploration campaigns. Portable X-ray fluorescence analysers (pXRF) and benchtop scanning electron microscopes with energy dispersive spectrometers (bSEM-EDS) are two

real-time acquisition instruments that can rapidly collect lithogeochemical and mineral chemical data in the field.

The first pXRF instrument was produced in 1991, following the introduction of cooled Si-PIN diodes and improvements to various components (Nicola et al., 2011). The first media analyzed were simple, with few interferences, e.g., archaeological ceramics and alloys. Since 1991, significant improvements such as the use of silicon drift detectors (SDD) and miniaturised X-ray tubes that can run at higher power, have made the pXRF technique increasingly applicable to the analysis of geological materials. The advantages of pXRF over lab XRF include the smaller size (portability), lower cost, and faster data collection, making it suitable for on-site lithogeochemical analysis. Applications of pXRF initially focused on environmental studies, with few related to mineral exploration. The pioneering work of Potts et al. (1995) provided a preliminary assessment of pXRF in the analysis of silicate rocks. Since then, there have been numerous studies that utilize pXRF in exploration geochemistry, including evaluations of pXRF performance in analyzing geological materials (e.g., Makinen et al., 2006, Morris, 2009, Haffert and Craw, 2009, Hall et al., 2012, 2014) and applications of pXRF to volcanogenic massive sulfide (Ross et al., 2014) and REE deposits (Simandl et al., 2014). Interactive applications of pXRF include using “fit for purpose” data for pathfinder elements in gold exploration (Arne et al., 2014) and the development of a workflow in the mining setting that highlights the importance of QA/QC control (Fisher et al., 2014). There are many other notable publications on the applications of pXRF to mineral exploration, however, it is beyond the scope of this paper to provide a complete review of the subject.

Unlike pXRF lithogeochemical analyses, there are few applications of field-based real-time mineral-chemical analysis. However, the development of benchtop scanning electron microscopes, equipped with energy dispersive spectrometers (bSEM-EDS), offers the possibility of collecting mineral composition data directly

in the field, in contrast with conventional mineral-chemical analysis from lab-based analytical instruments, e.g., scanning electron microscope with energy dispersive spectrometers and electron microprobe. The bSEM-EDS instrument can easily sit on a table in a field setting and samples do not require any preparation, such as polishing or carbon coating, prior to insertion into the instrument. This enables real-time imaging and EDS analysis at the sub-micron scale. Benchtop SEM instruments have been available for several years, but, to our knowledge, this technique has not been applied to mineral exploration. The current study combines pXRF with bSEM-EDS analysis as tools to improve decision-making in the field. In this study, these real-time analytical techniques are applied to Cu-Pd exploration at the Four Dams occurrence in the Eastern Gabbro of the Coldwell Alkaline Complex, northwestern Ontario, and the results are compared to those obtained by conventional laboratory analyses to establish the reliability of these techniques.

3.2 Study Area

3.2.1 Geological Setting

The Coldwell Alkaline Complex is the largest alkaline intrusive complex in North America (25 km diameter, 580 km² area) and is part of the Midcontinent Rift (Walker et al., 1993). It intruded the Archean Schreiber-White River greenstone belt at 1108 ±1 Ma (Heaman and Machado, 1992) during the early stages of the Midcontinent Rift (Miller and Nicholson, 2013). The Coldwell Alkaline Complex consists of a margin of ultramafic, gabbroic and meta-volcanic rocks that make up the Eastern Gabbro Suite (Good et al. 2015) and three intrusive centres composed predominantly of syenite and nepheline syenite (Mulja and Platt, 1982; Walker et al., 1993) (Fig. 3-1).

The Eastern Gabbro suite occurs along the outer margin of the Coldwell Alkaline Complex (Fig. 3-1). Good et al. (2015) identified nine major lithologies that were further grouped into three major distinctive magmatic series that were defined, from oldest to youngest, as meta-basalt, the Layered Series and the Marathon Series.

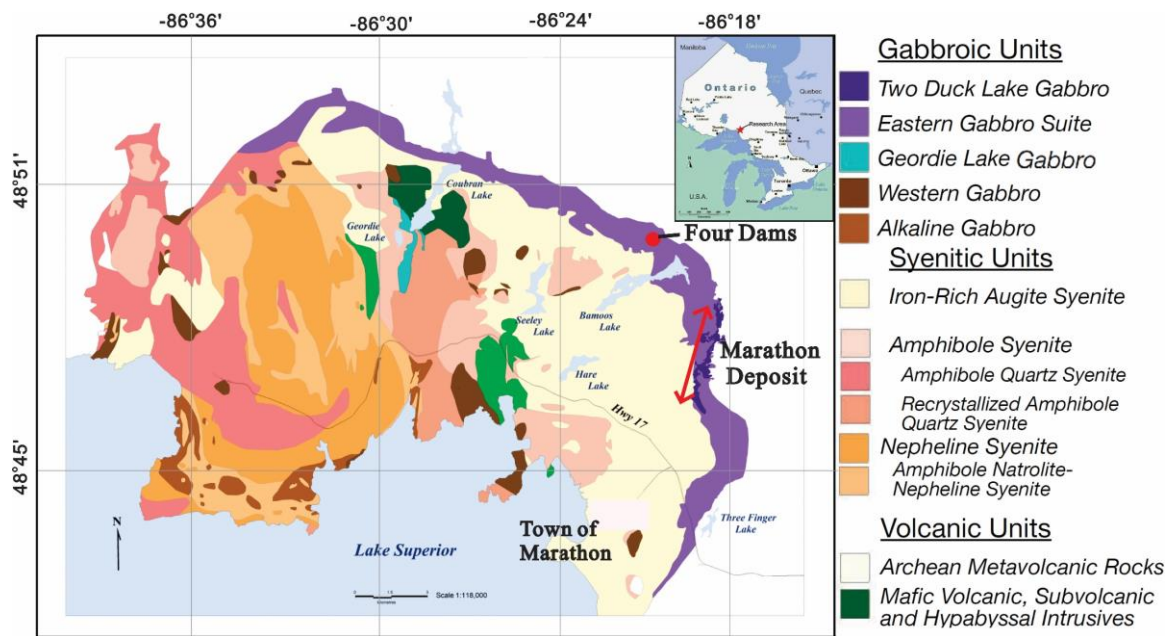

Figure 3-1. Geological map of the Coldwell alkaline complex. The location of Four Dams is represented by the red dot (Modified after Walker et al., 1993 and Good et al., 2015).

Meta-basalt (fine-grained gabbro in Good et al., 2015) occurs at or near the base of the Eastern Gabbro and comprises approximately one fifth to one-third of the volume of the Eastern Gabbro. It consists of pyroxene-hornfels-grade rocks that were intruded by the Layered and Marathon Series. The Layered Series is the next youngest unit and comprises the bulk of the Eastern Gabbro. It consists of massive to modally layered olivine gabbro with lesser amounts of weakly layered oxide augite melatroctolite, and less commonly gabbroic anorthosite. The Marathon Series is the youngest unit. It consists of numerous small intrusions composed predominantly of ophitic gabbro, apatite-bearing olivine clinopyroxenite, apatitic clinopyroxenite, and oxide melatroctolite (Good et al., 2015). The relative ages for these units were confirmed in the field by cross cutting relationships, particularly within the numerous units of igneous breccia.

Most of the copper and all of the known PGE mineralization within the Eastern Gabbro suite are hosted by the Marathon Series. In particular, at the Marathon deposit, the most important sub unit of the Marathon Series is the Two Duck Lake

gabbro, an ophitic gabbro and pegmatitic unit. Because of the significance of the Marathon Series as hosts for Cu-Pd mineralization, it is critical that the entire suite of Marathon Series intrusions can be distinguished from other Eastern Gabbro rocks for mineral exploration, particularly if it is possible to differentiate these units in the field. Note that although some disseminated chalcopyrite and pyrrhotite mineralization does occur in the Layered Series, it is associated with albite-actinolite alteration and contains only trace PGE (<0.005 ppm).

The Eastern Gabbro in the Four Dams area is located approximately 3 km northwest of the Marathon Cu-Pd deposit (Fig. 2-1) and contains units of both the Layered Series and Marathon Series. The Four Dams area is thus an ideal setting to establish whether pXRF and bSEM-EDS can be combined to establish an igneous stratigraphy that could be used to help guide future exploration.

3.2.2 Drill Hole FD-13-34

Drill hole FD-13-34 (Fig. 3-2) was selected because it intersects a complete section of igneous stratigraphy at the Four Dams occurrence, including units of both Layered Series and Marathon Series. The hole was drilled at an azimuth of 32.9° and dip of 69.6° for 375 m. The Layered Series at Four Dams consists of layered olivine gabbro and oxide augite melatroctolite and the Marathon Series consists of apatite-bearing clinopyroxenite, oxide melatroctolite, and a minor amount of ophitic gabbro, similar to the Two Duck Lake gabbro at the Marathon Deposit.

A 70 m thick sequence of oxide-rich units, consisting of, from top to bottom, oxide augite melatroctolite and oxide melatroctolite, separates the Layered Series from the Marathon Series. The oxide melatroctolite exhibits a sharp contact with the overlying Layered Series oxide augite melatroctolite. This contact is important because it forms a 350 m long stratigraphic marker horizon that facilitates interpretation of the local geology. Both oxide units are petrographically similar, but essentially belong to two different igneous series, i.e., the oxide augite melatroctolite is within the PGE barren Layered Series whereas the oxide

melatroctolite is in the Marathon Series and potentially hosts PGE mineralisation. Being able to differentiate both oxide units is important, not only because the oxide melatroctolite is potentially mineralized, but it can help define the contact between the barren Layered Series and the PGE mineralised Marathon Series.

Two types of igneous breccia occur within drill hole FD-13-34 and are representative of breccia units found throughout the Four Dams area. The first type occurs between 47 and 60 m down the hole and consists of xenoliths of meta-basalt rocks cut by Marathon Series intrusions. The second type occurs between 297 and 316 m down the hole and consists of Layered Series units cut by Marathon Series intrusions.

Two types of Cu-Pd mineralization occur in drill hole FD-13-34. The first type occurs within the Layered Series between 13 and 65 m down the hole and contains up to 0.41 % Cu and trace (<0.005 ppm) Pd (unpublished Stillwater Canada Inc. assay). The second type occurs primarily within the Marathon Series apatitic clinopyroxenite unit between 270-278 m and 290-336 m down the hole and contains up to 0.72% Cu and 0.56 ppm Pd (unpublished Stillwater Canada Inc. assay).

Figure 3-2. Gabbro units and sampling locations for drill hole FD-13-34.

3.2.2.1 Layered Series

The olivine gabbro of the layered series at Four Dams is medium to coarse-grained (1-3 mm) with modal layering defined by a gradational variation in the abundance of plagioclase. The gabbro has an intergranular texture (Fig. 3-3A) and is mainly composed of, in decreasing order of abundance, euhedral plagioclase (40-60 modal%), subhedral clinopyroxene (15-30 modal%), subhedral olivine (10-15 modal%), magnetite (~5 modal%), and less than 6 modal % fine-grained apatite that is typically enclosed in, or interstitial to, olivine and plagioclase.

The oxide augite melatroctolite is medium- to coarse-grained and has similar textures to the layered olivine gabbro. It is distinguished by the presence of abundant (10 to 30 modal %) disseminated magnetite (Fig. 3-3B). The mineral composition of this unit comprises, in approximate decreasing order of abundance, olivine (20-45 modal%), plagioclase (15-30 modal%), clinopyroxene (10-20 modal%), magnetite, and apatite (<10 modal%). Olivine and clinopyroxene are euhedral, and occur between subhedral to anhedral plagioclase clusters. The oxide augite melatroctolite contains disseminated sulfide minerals (2-3 modal %) that are dominated by fine-grained pyrrhotite with trace chalcopyrite.

3.2.2.2 Marathon Series

Where the Marathon Series crosscuts Layered Series rocks in drill hole FD-13-34, intrusive contacts are sharp and lack chilled margins. The oxide melatroctolite and the apatitic (olivine) clinopyroxenite (see below) are interpreted to be part of the Marathon Series because they also commonly occur as thin lenses within the main body of the Two Duck Lake gabbro at the Marathon deposit and typically contain disseminated chalcopyrite and pyrrhotite with elevated PGE concentrations (Good et al., 2015).

The oxide melatroctolite is medium-grained and equigranular, which consists of subhedral magnetite (40-60 modal %), subhedral olivine, clinopyroxene, and plagioclase (the total of the three minerals is less than 30 modal%), and from 2 to

30 modal % euhedral apatite. Between 247.8 and 263.4 m, the oxide melatroctolite becomes coarser grained (2-3 mm) and is characterized by coarse-grained plagioclase laths that vary from 20 to 50 modal % (Fig. 3-3C).

The apatitic (olivine) clinopyroxenite is an apatite-rich rock which consists of up to 30 modal % apatite. It consists mainly of medium- to coarse- grained subhedral olivine (10-20 modal%), clinopyroxene (30-60 modal%), and magnetite (~10 modal%) with interstitial plagioclase (5-10 modal%) and euhedral apatite (Fig. 3-3D), and commonly contains disseminated pyrrhotite and chalcopyrite. Some chalcopyrite occurs intergrown with plagioclase that replaces early plagioclase (Figs. 3-3E and 3F). Chemical (EDS) analyses (discussed later) shows that the late plagioclase is more calcic than the early plagioclase.

The ophitic gabbro is coarse grained (2-4 mm) and is distinguished by an ophitic to subophitic texture. It is composed of, in approximately decreasing order of abundance, subhedral plagioclase (40-70 modal%), subhedral clinopyroxene (15-30 modal%), euhedral to subhedral olivine (5-10 modal%), and less than 10 modal% magnetite and apatite. Although this unit constitutes a major part of the Marathon Series and is the main host to the Cu-PGE mineralization at the Marathon deposit (Two Duck Lake gabbro), it occurs as thin discontinuous intrusions in the Four Dams area.

Figure 3-3. Representative thin section scans and photomicrographs from FD-13-34. (A) The Layered Series olivine gabbro with typical equigranular and intergranular texture; (B) The Layered Series oxide augite melatroctolite showing abundant magnetite (25% modal) interstitial to Ol, Cpx, and Plag; (C) The coarse-grained oxide melatroctolite of the Marathon Series within the Marker Horizon, which is relatively enriched in Plag; (D) The apatitic clinopyroxenite of the Marathon Series shows Cpx cumulates with interstitial Plag and Mt; (E) Cross-polarized transmitted light photomicrograph showing early Plag rimmed by late Plag intergrown with Ccp; (F) Reflected-light photomicrograph showing Ccp; some Ccp grains are rimmed by hydrothermal Mt. Abbreviations Ol: olivine; Cpx: clinopyroxene; Plag: plagioclase; Mt: magnetite; Chl: chlorite; Bio: biotite; Ap: apatite; Act: actinolite; Ccp: chalcopyrite; Po: pyrrhotite.

3.3 Methods

3.3.1 Sample preparation

Seventy-two powdered samples were collected by grinding 1 m-long channels along the drill core approximately 2 mm wide and 1 cm deep using a Thermo Scientific

portable grinder. Sample locations for powdered samples are given in Figure 3-2. A typical sample required 2 to 5 minutes to collect and produced ca. 10 to 200 μm of powder. A few pXRF analyses were made on powders that were re-ground, but this had little effect on the results. Samples were taken at intervals of ca. 4.5 m along the length of the drill hole. Cross-contamination was minimized by washing the collection vial, cleaning off the grinder blade, pre-contaminating the vial by grinding some of the sample, shaking the vial to coat the vial with the sample dust and dumping out the vial, and then collecting the powdered sample to be analyzed. All powders were then loaded into PREM-4331 XRF sample cups capped with 4- μm PREM-F2540 XRF sample cup films for the pXRF analysis.

The potential for contamination of Fe, Cr and Ni by the grinder blade was tested by sampling a piece of pure quartz. The pXRF analyses are presented in Table 2-2 and show that grinder blade-related contamination for most elements except Ni is insignificant, with less than 0.1 wt. % for most major elements and lower than the detection limit for trace elements. Approximately 100 ppm of Ni is added to each sample during grinding.

Twenty-three polished thin section blocks that were representative of the different gabbro units and styles of mineralization (e.g., chalcopyrite-rich, bornite-rich, and pyrrhotite-rich) were cut from drill core FD-13-34 (Fig. 3-2) for petrographic and bSEM-EDS analysis.

3.3.2 pXRF analysis

A Niton XL3t+ GOLDD+ pXRF analyzer equipped with a SDD, and a high energy, 50kV X-ray Ag anode tube was used in this study. All pXRF measurements were carried out on powders after calibrating the pXRF analyser using a suite of matrix-matched standards, including two U.S. Geological Survey reference materials, BHVO-2 basalt and W-2a diabase, and seven Marathon gabbro internal standards. This suite of standards covers a wide range of concentrations for elements measured in the current work: SiO_2 , Al_2O_3 , CaO, Fe_2O_3 (as total Fe), TiO_2 , K_2O , P_2O_5 , MgO,

Ba, V, Zr, Sr, Cu, and S. Major elements were determined using the instrument's 'mining mode', with two beams, whereas minor and trace elements were determined using the 'soil mode', with three beams; beam time for both modes was 60 s, as suggested by Hall et al. (2014) and Fisher et al. (2014). The QA/QC control throughout all analyses was carried out by analyzing two standards after each batch of unknown samples (20 samples typically). A blank standard (98.2 wt. % SiO₂) was analyzed at the beginning and the end of each batch measurement to monitor cross-contamination from the test stand and check for machine drift. Typically, a new calibration was conducted after every two batches of unknown samples. The intent was to acquire the highest quality of results and less-frequent calibration may have yielded a similar result.

3.3.3 Conventional whole-rock analysis

Whole-rock chemical analyses were carried out by the ALS Mineral Division in Vancouver on powders that were initially analyzed by pXRF. After further pulverization, major and trace elements were determined by ICP-AES and ICP-MS, after lithium borate fusion on a minimum 2 g of pulp samples. Total S was determined using a Leco combustion furnace on 0.01 to 0.1 g of sample, in which the sample is heated to roughly 1350°C in an induction furnace. SO₂ is produced through a reaction with oxygen and is measured by an infra-red detector. Ferrous Fe was determined by H₂SO₄-HF acid digestion and titration on 1 g of sample. Quality-control was achieved by analysing a wide array of standards, blanks, and duplicates after each batch of samples, in accordance with ALS geochemical quality-control procedures. Some additional data from Stillwater Canada Inc. is also used to compare S and Cu values. These were also analyzed by ALS; S by Leco, as above, and Cu by aqua regia dissolution and ICP-AES analysis.

3.3.4 Benchtop SEM-EDS analysis

The major constituents of plagioclase, clinopyroxene, and olivine were determined using a JEOL JMC-600 NeoScope SEM equipped with a JEOL JED-2300 energy

dispersive X-ray analyser at Western University. Analyses were conducted using 15 kV accelerating voltage, a high probe current, a working distance of 19 mm, and 30 to 40 μm beam size with standardless ZAF corrections. Unpolished thin section blocks were analyzed under low vacuum mode and carbon-coated polished thin sections were analyzed under high vacuum mode.

3.3.5 Electron microprobe analysis

Electron microprobe analyses were carried out using a JEOL JXA-8530F field emission probe at Western University. Microprobe analyses were conducted on the same carbon-coated polished thin sections that were analyzed by bSEM-EDS. Analyses were conducted using a 15 kV, 20 nA beam. The beam was focused to a 1 μm spot for analyzing olivine and clinopyroxene, and to a 5 μm spot for analysing plagioclase. The peak counting time was 30 s for all elements and background counts were a total of 30 s. A variety of synthetic and natural standards were used to calibrate different elements during probe analyses.

3.4 Comparison of field portable results to lab-based analyses

3.4.1 pXRF

All major and trace element concentrations determined by pXRF and by ICP-AES, ICP-MS and IR are provided in Table 3-1. The down-hole profile of pXRF data relative to lab-based data (Fig. 3-4) shows that the pXRF data broadly replicate the lithogeochemical patterns defined by the conventional data. The correlation coefficients have R^2 values of > 0.9 for all elements, except for MgO (Table 3-2). Mg is the lightest element and thus should have the poorest precision and accuracy by pXRF. However, the MgO R^2 value is 0.77, which is still a reasonable correlation between these two methods. Therefore, pXRF is able to provide analyses comparable to lab-based analyses for the elements included in the current study.

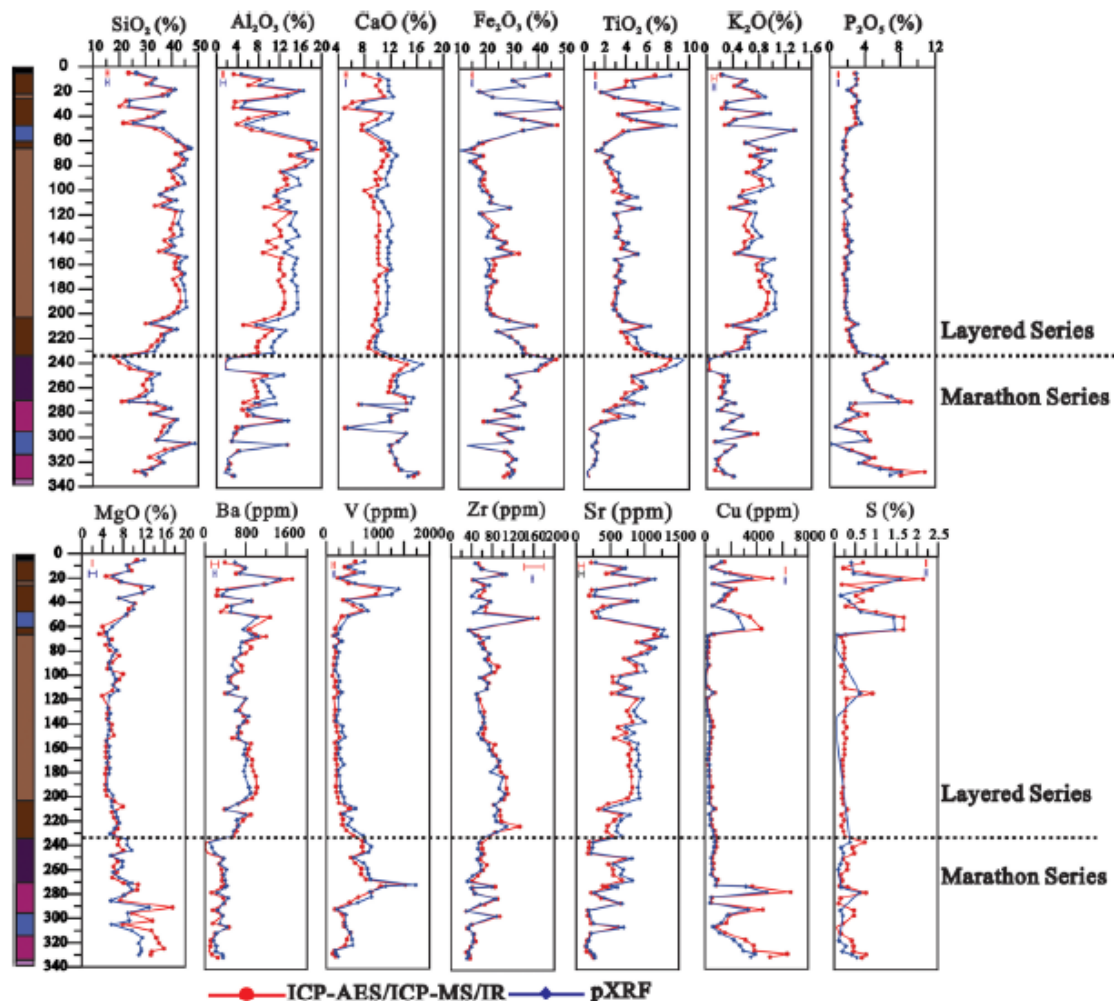

Figure 3-4. Down-hole comparisons between pXRF and ICP-AES/ICP-MS/IR whole-rock analyses, error bar (top of each diagram) represents error with 95% confidence (2σ) determined through repetitive analyses. Legend as in Figure 3-2.

To further illustrate the accuracy of the pXRF analyses, the differences of pXRF results relative to lab-based results (RD) are shown on whisker-box diagrams (Fig. 3-5). pXRF results for major elements, excluding Al_2O_3 , generally have an accuracy in the range of $\pm 20\%$ RD (in the 25 to 75 percentile range); accuracy for pXRF Al_2O_3 is between 10% and 35% RD (in the 25 to 75 percentile range), which is inferior to that for other major elements. For minor and trace elements, Ba, Sr and Zr have better accuracy than other elements, with the majority of RD values within $\pm 20\%$ (in the 25 to 75 percentile range). By contrast, the accuracy for pXRF S, V,

and Cu is inferior, and most of their RD values are outside the $\pm 20\%$ range (in the 25 to 75 percentile range). Since there are excellent correlations between pXRF and ICP-AES/ICP-MS/IR Al_2O_3 , V, Cu, and S analyses, recalibration can be applied to improve data accuracy. Figure 3-6 shows the improvement of accuracy for pXRF Cu and S analyses after such recalibration. The pXRF data accuracy and precision reported here are similar to those evaluated by previous studies of Hall et al. (2014), Piercey and Devine (2014), and Ross et al. (2014).

Table 3-1. Comparisons of pXRF analyses with ICP-AES, ICP-MS and IR analysis for major oxides and trace elements. Fe₂O₃^T means the total Fe is reported as Fe₂O₃, 95% confidence errors (2σ) are listed in brackets. RD represents relative differences between pXRF and ICP-AES, ICP-MS and IR analyses. LOD means limit of detection, nd means not determined, N/A=not available.

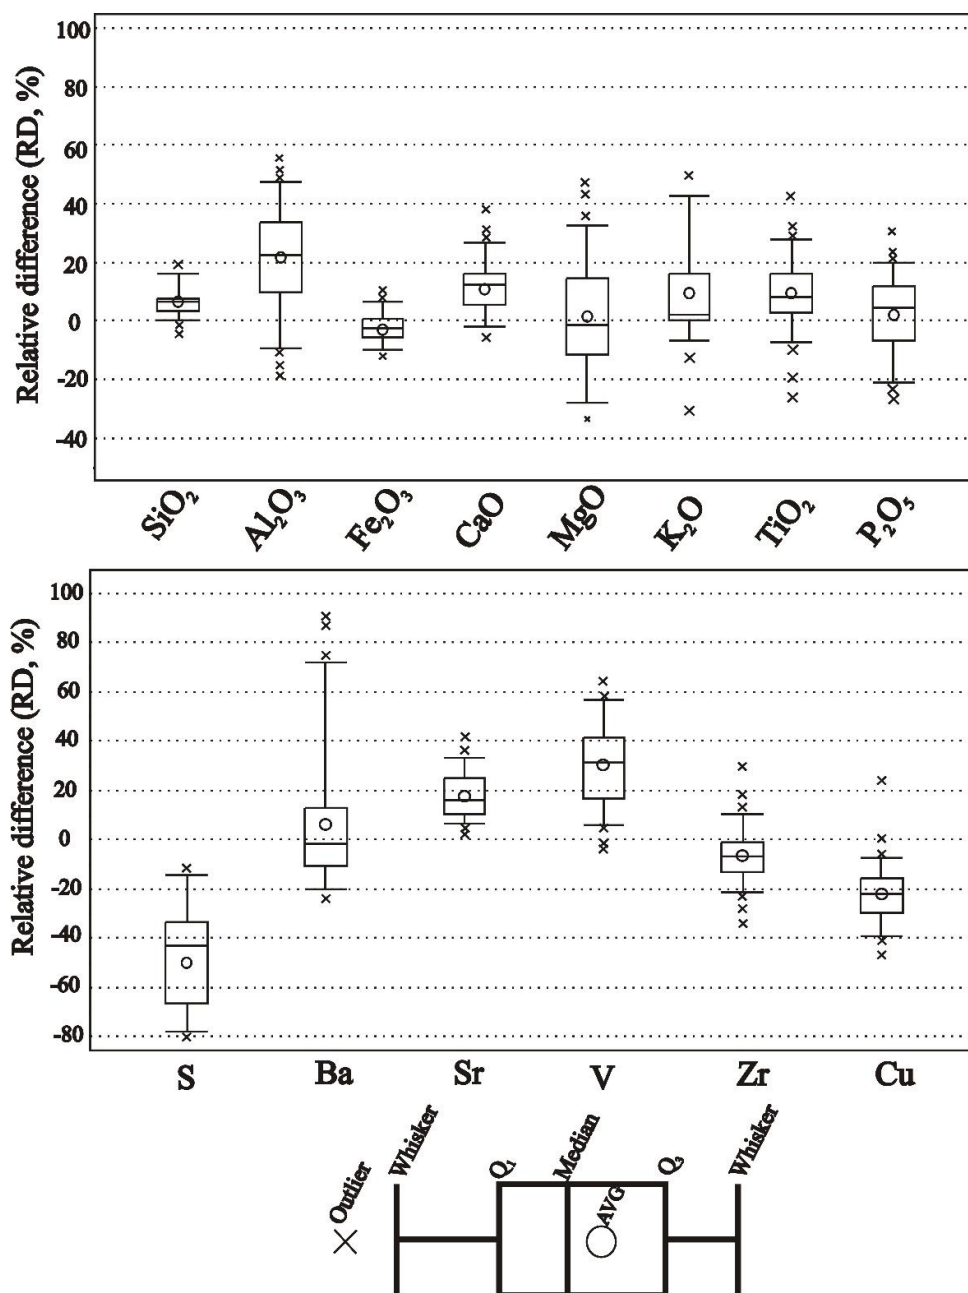

Figure 3-5. Box-and-whisker diagram showing relative differences between pXRF and ICP-AES/ICP-MS/IR whole-rock analyses for selected major and trace elements. Box and whisker plots are uniform in their use of the box: the bottom and top of the box are always the 25th and 75th percentile (the lower and upper quartiles, respectively), and the band near the middle of the box is always the 50th percentile (the median). The small circle is the average and the lines on the ends are the minimum and maximum values, crosses are outliers.

Figure 3-6. Binary diagrams correlating pXRF analyses with ICP-MS/IR whole-rock analyses for Cu and S before and after further corrections.

3.4.2 Benchtop SEM

It is not possible to carry out a full calibration and ZAF correction with matrix-matched materials using the bSEM-EDS. However, mineral ratios rather than absolute concentrations are commonly used to examine mineral chemical variations in suites of magmatic rocks. In this study the Mg#s (molar $\text{MgO}/(\text{MgO}+\text{FeO}) \times 100$) of olivine and clinopyroxene, and the An% (molar $\text{Ca}/(\text{Ca}+\text{Na}) \times 100$) of plagioclase were determined, because these are useful indices for assessing magma evolution and mechanisms for forming magmatic PGE mineralization (Barnes, 2004; Mungall and Naldrett, 2008). The highest quality bSEM-EDS data will be obtained from carbon-coated polished thin sections, but unpolished cut blocks were also analyzed to establish field portability. Consequently, Mg#s of olivine and clinopyroxene, and An% of plagioclase determined by bSEM-EDS for carbon-coated polished thin sections and unpolished blocks are compared to electron microprobe data (Table 3-3 and Figure 3-7).

The precision of electron microprobe analyses was determined by analyzing the same spot 10 times: results are ± 0.07 for Mg# of olivine, ± 0.30 for Mg# of

clinopyroxene, and ± 0.15 for plagioclase An% (1 sigma standard deviation). These standard deviations (machine error) are well below the sample variability that were determined through wavelength-dispersive spectrometer (WDS) analyses conducted on 3 or 4 grains of each mineral type in each sample (Table 3-3). Machine error for bSEM-EDS analyses of carbon coated polished thin sections are 0.51 for Mg# of olivine, ± 1.0 for Mg# of clinopyroxene, and ± 0.63 for An% of plagioclase (1 sigma standard deviation). These values are higher than those for the electron microprobe. The sum of the standard deviation of natural variation of all three minerals (determined from 3 or 4 grains per sample) and the machine error for the electron microprobe analyses is $< \pm 1$ to ± 3 , compared to ± 1 to ± 4 for bSEM-EDS analysis for carbon coated polished thin sections (Table 3-3, Figure 3-7).

For the bSEM-EDS analysis of unpolished blocks it is necessary to use the low vacuum mode to reduce charge build-up from electrons accumulated on non-carbon coated surfaces, but nevertheless it is possible to measure a mineral directly in the field. Considering that rough surfaces will diffract X-rays from the detector, which results in artificially low measured concentrations (Morros, 2009; Fisher et al, 2014), it is difficult to make accurate measurements on unpolished blocks. Whereas data accuracy may be lower for unpolished blocks, the data may still be of sufficient quality to aid decision making in the field. To evaluate this, we first determined the machine error of Mg#s for olivine and clinopyroxene and An% for plagioclase by repeat analysis of single grains in the unpolished blocks. These errors are ± 1.9 for Mg# of olivine, ± 1.7 for Mg# for clinopyroxene and ± 2.0 for An% (1 sigma standard deviation). As anticipated, the errors are higher than those from carbon coated polished thin sections, but they are still of high enough precision to be useful for mapping igneous stratigraphy. Next, the bSEM-EDS analyses of 11 unpolished blocks are compared to their probe counterparts conducted on corresponding carbon-coated polished thin sections (Table 3-3 and Fig. 3-7). The correlation between bSEM-EDS and probe analyses is excellent ($R^2 > 0.9$) for Mg#s of olivine

and clinopyroxene, and reasonable ($R^2=0.69$) for An% of plagioclase, indicating bSEM-EDS analyses of unpolished blocks are comparable to their probe counterparts. However, where unpolished blocks were analyzed, repeated measurements of different mineral grains in each sample show higher variability compared to analyses of carbon-coated polished thin sections. Standard deviation values of the above ratios for unpolished blocks (combination of machine error and natural variability) are typically between 3 and 8. However, the analysis of unpolished blocks is of sufficient precision to aid exploration geologists with decision-making in the field and it should be possible to improve analyses from cut blocks by polishing them in the field.

We have also compared bSEM-EDS analyses of carbon-coated polished thin sections to microprobe analyses, with both sets of analyses conducted on the same grains (Table 3-3 and Fig. 3-7). The correlations between bSEM-EDS and electron microprobe analyses are excellent for Mg# of olivine ($R^2=0.90$) and An content of plagioclase ($R^2=0.85$), and reasonable for Mg# of clinopyroxene ($R^2=0.73$).

In addition, sample precision for bSEM-EDS analyses of carbon-coated polished thin sections are improved substantially when compared to bSEM-EDS analyses of unpolished blocks (Table 3-3 and Fig. 3-7). Figure 3-8 compares down-hole variations in Mg#s of olivine and clinopyroxene, and An% of plagioclase between probe analyses and bSEM-EDS of unpolished blocks and carbon-coated polished thin sections. The carbon-coated polished thin sections (bSEM-EDS) and probe analyses methods display broadly similar down-hole variations throughout the igneous stratigraphy, including both the Layered Series and the Marathon Series, indicating interpretations regarding the igneous stratigraphy based on bSEM-EDS analyses will be comparable to their probe counterparts. Fewer data points were collected from unpolished blocks, but the downhole variation is similar to bSEM-EDS analyses from carbon-coated polished thin sections. However, it must be kept in mind that bSEM-EDS analysis in the current work is semi-quantitative, without

calibration using standards, and, in addition, peak overlaps (e.g., overlaps for Cr, Ti, V) are common issues for EDS analysis. The data quality of bSEM-EDS analysis will therefore inevitably be less accurate and precise than those determined from WDS analysis on an electron microprobe, particularly with respect to data accuracy.

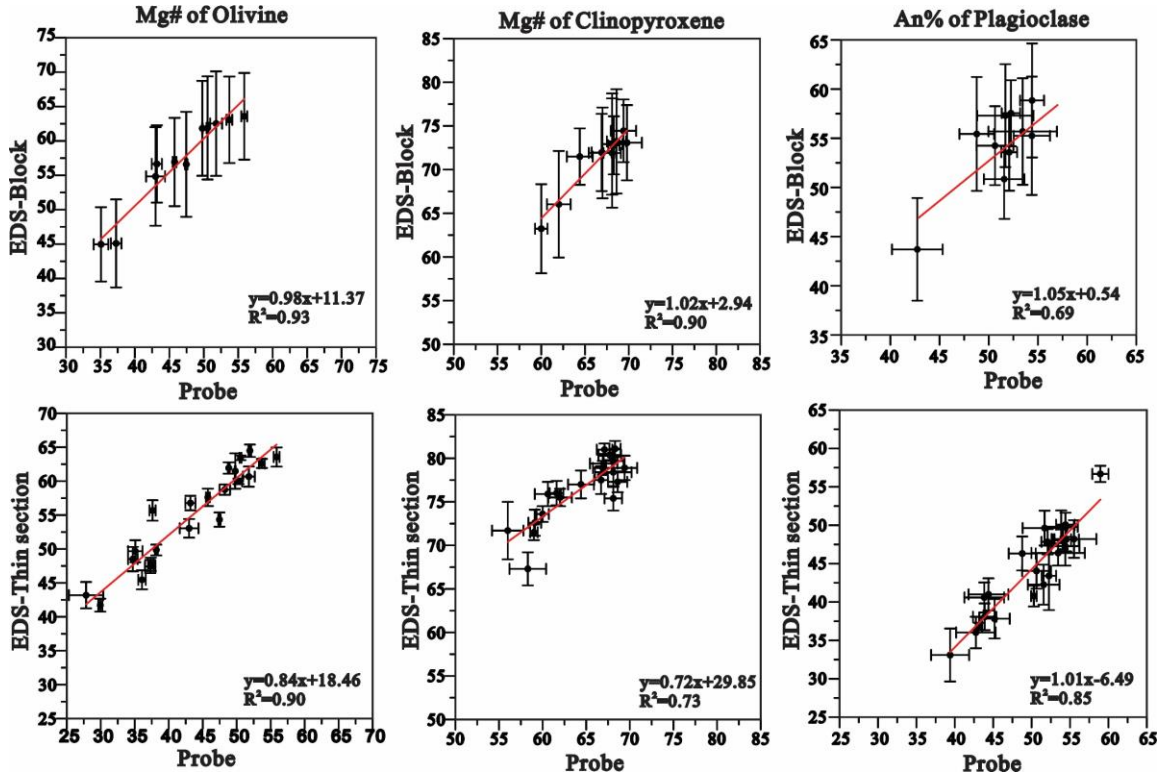

Figure 3-7. Correlation between bSEM-EDS and probe analyses, EDS analyses were conducted on unpolished blocks and carbon-coated polished thin sections separately. The red line represents the best-fit regression line correlating EDS analyses with probe analyses. Error bars represents 1σ sample errors determined through EDS analyses conducted on 3 or 4 grains of each mineral type in each sample, and multiple spot analyses were conducted on each mineral grain. Average values are correlated in this figure.

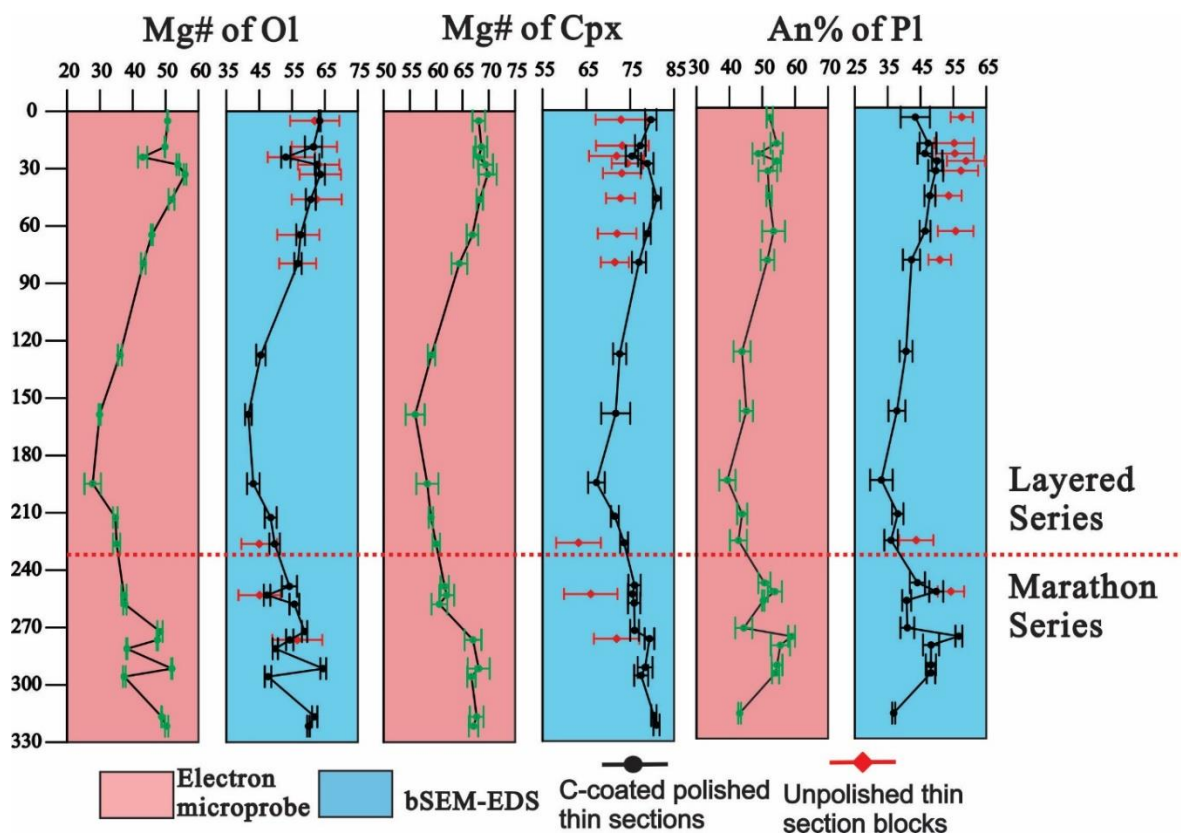

Figure 3-8. Down-hole comparisons between bSEM-EDS (unpolished thin section blocks and carbon-coated polished thin sections) and WDS electron microprobe analyses.

Table 3-3. Comparison of mineral chemical data from electron microprobe with bSEM-EDS analyses of carbon-coated polished thin sections and unpolished offcut blocks, nd means not determined, AVG means average values, SD means 1 σ sample errors determined through EDS analyses conducted on 3 or 4 grains of each mineral type in each sample, and multiple spot analyses were conducted on each mineral grain.

3.5 Geochemistry of igneous stratigraphy

3.5.1 Lithochemistry

As shown above, the variation of the molar Mg#s for olivine and clinopyroxene is important. However, it is difficult to estimate this ratio for whole-rock compositions because of the presence of magnetite. However, most of the whole-rock TiO₂ is contained in magnetite. The laboratory analyses include the determination of FeO by titration from which the whole-rock Fe₂O₃ was calculated by difference from total Fe₂O₃. Figure 3-9 shows a linear correlation between laboratory-based Fe₂O₃ and TiO₂. The data was fit by a least square to a linear equation: Fe₂O₃ (wt. %) = 1.3966TiO₂ (wt. %) + 1.2732. This equation was then applied to pXRF TiO₂ data to deduce pXRF Fe₂O₃ concentrations, after which, the pXRF FeO data was calculated by subtracting pXRF Fe₂O₃ from pXRF total Fe₂O₃. This allowed pXRF whole-rock Mg numbers to be calculated: Mg#_{WR} is molar MgO /(MgO+FeO)*100 (Table 3-4).

Table 3-4. pXRF whole-rock V/Ti, FeO, and Mg#_{WR} of different rock units down drill hole FD-13-34.

*95% confidence error calculated based on the equation $\sigma_{(A/B)} = A/B * ((\sigma_A/A)^2 + (\sigma_B/B)^2)^{1/2}$

Figure 3-9. The correlation between lab-based whole-rock TiO_2 and Fe_2O_3 contents, by fusion ICP-AES. Error bar represents 2σ analytic precision determined through replicate analyses.

The key pXRF lithogeochemical parameters for defining the different igneous units are Mg\#_{WR} , CaO, P_2O_5 , Ba, and Zr and the V/Ti ratio (Table 3-1 and Table 3-4). Figure 3-10 shows box and whisker plots of these parameters and their down-hole variations are plotted in Figure 3-11. In Figure 3-10, Layered Series rocks have lower CaO, P_2O_5 and V/Ti ratios, and higher Ba and Zr contents than Marathon Series rocks. However, the Mg\#_{WR} values of the Layered Series rocks are similar to those of the Marathon Series rocks. Good et al. (2015) also observed a lower V/Ti ratio in Layered Series rocks compared to Marathon Series rocks at the Marathon deposit. Thus, the V/Ti ratio seems to be a good discriminant between these two Series throughout the Eastern Gabbro. The higher Ba contents in the Layered Series gabbros is also consistent with the data of Shaw and Penczak (1996) who recognized

Ba-rich biotite in this series. In addition, there is a positive correlation between pXRF K₂O and Ba for samples in this study (Fig. 3-12), indicating that Ba is controlled by biotite (negligible K-feldspar is present in the samples examined in this study, although K-feldspar is observed elsewhere in the Eastern gabbro).

Figure 3-11. Down-hole variations in pXRF whole-rock V/Ti, Mg#_{WR}. Note that all data were related to pXRF analyses on powders, the red dashed line indicates the contact, and lithology legend can refer to Figure 3-2.

Figure 3-12. Relationship between K_2O and Ba contents as represented by pXRF analysis of powders, all data refer to units in the Layered Series of the Four Dams area. Error bar represents 2σ analytic precision determined through replicate analyses.

Down-hole pXRF whole-rock chemistry can also be used to differentiate between the Layered and Marathon Series rocks. P_2O_5 contents in the Layered Series are nearly constant, whereas the Marathon Series rocks have variable P_2O_5 contents (representing apatite-rich cumulate layers rather than interstitial apatite) that overall increase with depth (Fig. 3-4). Down-hole pXRF variations of Zr contents in the Layered Series are variable but generally increase with depth. By contrast, the Marathon Series rocks have decreasing Zr contents with depth (Fig. 3-4). The down-hole variation in pXRF V/Ti ratio of the Layered Series gabbros is nearly constant at around 0.015, in contrast to that of the Marathon Series rocks where it generally

increases with depth from 0.015 to 0.1 (Fig. 3-11). The $Mg\#_{WR}$, although similar in the Layered and Marathon Series, does show subtle variation. The $Mg\#_{WR}$ decreases with depth in the Layered Series gabbros (reverse differentiation) versus the Marathon Series rocks, which have an increase in $Mg\#_{WR}$ with depth (normal differentiation) (Fig. 3-11).

The concentrations of Hf, Nb, Ta, and Zr in the different rock units from the ICP-MS analyses are given in Table 3-5 and their down-hole variations are shown in Figure 3-13. The Layered Series gabbros contain Hf, Nb, Ta, and Zr concentrations in the range 0.9 to 4.0 ppm, 16 to 73 ppm, 0.7 to 3.0 ppm, and 37 to 168 ppm, respectively, and all of these elements generally increase downward in the Layered Series gabbros. The Marathon Series, by contrast, has variable Hf, Nb, Ta, and Zr contents that overall continually decrease with depth. The down-hole variation in pXRF Zr is included in Figure 3-13 for comparisons, which is broadly similar to down-hole variations of ICP-MS Hf, Nb, Ta, and Zr.

3.5.2 bSEM-EDS mineral chemistry

Down-hole variations in the Mg#s of olivine and clinopyroxene, and the An% of plagioclase are shown in Figure 3-14. The Layered Series gabbros show an overall downward decreasing trend in Mg# of olivine, Mg# of clinopyroxene, and An% of plagioclase. By contrast, the Mg#s of olivine and clinopyroxene, and An% of plagioclase gradually increase downward in both the oxide melatroctolite and the apatitic clinopyroxenite in the Marathon Series.

Average compositions are black points with minimum and maximum compositions represented by the grey envelope. Red dashed line represents the contact between the Layered Series and the Marathon Series. Legend for lithology as in in Figure 3-2.

3.6 Discussion

3.6.1 The application of pXRF and bSEM-EDS to Cu-Pd mineral exploration

As discussed above, applications of pXRF to mineral exploration has been demonstrated by many studies, whereas, to our knowledge, this is the first

application of bSEM-EDS to mineral exploration. In this section, we examine the combination of pXRF and bSEM-EDS to increase efficiency in mineral exploration. The down-hole variations in Cu and S values from pXRF are compared to exploration assay data from drill hole FD-13-34 (Figure 3-15 and Table 3-6). There is a strong correlation between the two patterns, despite the different sampling intervals (assay data were determined on continuous 2 m sample intervals, whereas samples for this study were collected over 1 m intervals at 3 m spacing). These results show that pXRF is able to quantify Cu concentrations on powders down to at least 100 ppm. In addition, two zones of mineralization: a zone characterized by low Cu/S ratios at the top of the Layered Series and a zone characterized by high Cu/S ratios at the bottom of the Marathon Series (Fig. 3-15) are identified in drill hole FD-13-34 by both exploration assay and pXRF data. The Pd abundance in the upper zone with low Cu/S is at or below detection limits of ICP-MS analysis, whereas mineralization in the Marathon Series with high Cu/S is PGE enriched (unpublished Stillwater Canada data), suggesting high Cu/S ratios seem to be a proxy for PGE mineralization at this locality. Figure 3-16 further illustrates how the pXRF data can be plotted to identify two different Cu/S ratios corresponding to the two mineralized zones described above. Whereas pXRF is unable to detect PGE, bSEM-EDS can be used as a complimentary technique to verify Pd mineralization.

Figure 3-15. Down-hole comparisons between pXRF and ICP-MS/IR Cu and S results; two different mineralized zones are shaded in different colours. Legend for lithology as in Figure 3-2.

Figure 3-16. Two similar Cu/S trends shown by both pXRF and laboratory-based whole-rock data. 2σ error was determined through replicate analyses.

Several platinum group minerals (PGM) in Marathon Series gabbros within the high Cu/S ratio zone were identified using bSEM-EDS (Figs. 3-17 and 3-18) through scanning the thin sections and thin section blocks. Time needed for identification of PGM in either thin section or thin section block varies, but normally less than 30 minutes were spent on identifying PGM in each PGM-hosted sample. The PGM in Figure 3-17 are from carbon-coated polished thin sections, but the Ag-Au alloy shown in Figure 3-18 is from an unpolished block. This demonstrates that the bSEM-EDS can be used to identify mineralization in saw-cut drill core in the field, without having to wait for assays. In another example, down-hole variations in whole-rock MgO or Mg#_{WR} from pXRF (Figs. 3-4 and 3-11) are difficult to interpret

without knowledge of mineral chemistry. However, bSEM-EDS analyses show a “saw-tooth” pattern for Mg# of olivine between depths of 270 and 290 m (within the high Cu/S zone) (Figs. 3-8 and 3-14). Similar patterns have been interpreted by Good et al. (2015) as magma recharge conduits that are favorable for PGE mineralization. Thus, the combination of pXRF and bSEM can be used in the field to identify possible recharge zones. The last example is the replacement of early plagioclase by later more-calcic plagioclase, An50 by An60 by bSEM-EDS analysis (Fig. 3-19). This texture is notable because chalcopyrite is intergrown with the later plagioclase (Figs. 3-3E and 3F) and precious metals are associated with the chalcopyrite (Fig. 3-19). Similar textures were described in the Marathon Main zone by Good and Crocket (1994), thus another application of bSEM-EDS is to identify favourable textures in the field.

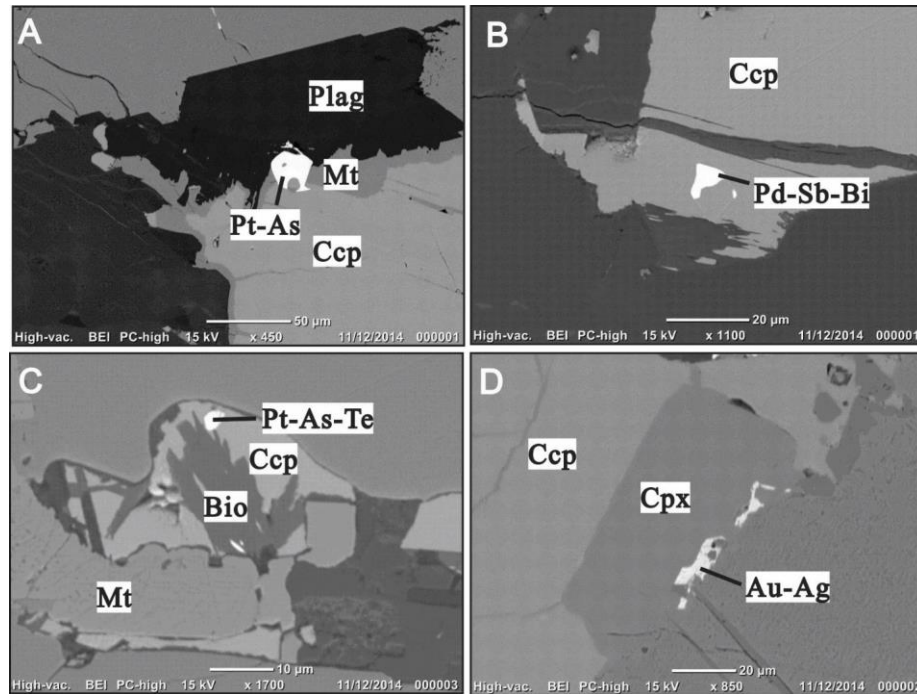

Figure 3-17. bSEM-BSE images showing PGM grains in the apatitic clinopyroxenite unit in the Marathon Series. Figure 3-18. Location of Ag-Au alloy in an unpolished thin section block using the bSEM-EDS. (A) Sawed block from drill core with chalcopyrite mineralization; (B) bSEM-BSE image showing the Ag-Au alloy enclosed in Bio, adjacent to Ccp; (C) EDS spectrum of above Ag-Au alloy. The red circle gives the location of the sulfide that hosts the Ag-Au alloy. Note that Pd and Pt assay values for this sample (556 ppb Pd and 190 ppb Pt) are quite low. Several Pt and Pd alloys were found elsewhere, but BSE images of them are of poor quality. Abbreviations: Ccp- Chalcopyrite, Bio- Biotite.

Figure 3-19. Two stages of plagioclase identified using bSEM-EDS. (A) CaK α X-ray map showing the replacement of early less-calcic plagioclase by late, more-calcic plagioclase; (B) BSE image showing a Ag-Te mineral inclusion hosted by one of the chalcopyrite grains (indicated using the white box in Figure 3-19A) occurring intergrown with the late plagioclase.

3.6.2 The application of pXRF and bSEM-EDS to mapping igneous stratigraphy

This study shows that the combination of pXRF and bSEM-EDS can be used in the field to map igneous stratigraphy in a manner similar to laboratory-based studies that combine whole-rock lithogeochemistry and mineral chemistry (Li et al., 2000; Egorova and Latypov, 2013). The interpretation of results from only one method is more difficult. In this study the Layered Series gabbros including the oxide augite melatroctolite (barren) and the Marathon Series gabbros including the oxide melatroctolite (potentially mineralized) can be distinguished from variations in the major-element and trace-element abundances, e.g., Layered Series rocks contain lower CaO, P₂O₅ and V/Ti ratio and higher Ba and Zr contents than Marathon Series rocks. We have also shown that Zr, determined by pXRF can serve as a proxy for other high field strength elements and the down-hole variations of these highly incompatible element abundances is useful to help differentiate between the PGE-barren Layered Series and the PGE-enriched Marathon Series (normal differentiation for the Marathon Series gabbros versus reverse differentiation for the Layered Series gabbros). Shaw (1997) described normal and reverse trends for mineral compositions in the Layered Series. In this study we have shown that these

trends can also be recognized using bSEM-EDS, in particular for the Mg#s of olivine and clinopyroxene, and An% of plagioclase. It is the combination of whole-rock lithogeochemical and mineral chemical data that allow for a more robust interpretation of the igneous stratigraphy. Unravelling the mechanisms that caused the reverse and normal trends for the Layered Series and the Marathon Series, respectively, is beyond the scope of this paper. The significance of this work is that variations and trends in the various igneous rocks in the Coldwell Alkaline Complex have been characterized using a combination of field portable techniques. This methodology can be used to guide sampling in an iterative fashion in the field, which increases the efficiency of both mineral exploration and academic research.

3.7 Conclusions

The reliability of results from the field portable pXRF and bSEM-EDS are demonstrated in the current study. Both portable instruments are able to provide analyses comparable to their lab-based counterparts. In addition, pXRF is capable of estimating Cu grade down to ca. 100 ppm and reliably identifies different Cu/S values that can assist in Cu-Pd mineral exploration because, for mineralization in the Coldwell Alkaline Complex, high Cu/S ratios serve as a proxy for potential PGE mineralization. The technique of bSEM-EDS can also be used to identify PGM grains directly in the unpolished blocks. The ability to rapidly identify PGE mineralization in the field can improve the decision-making process in exploration. This study was also successful in differentiating between petrographically similar gabbros that belong to two different magmatic series using pXRF and bSEM-EDS: the Marathon Series, which hosts PGE mineralization, and the Layered Series, which is barren of PGE mineralization. Overall, the combination of pXRF and bSEM-EDS can greatly improve sampling and hypothesis testing in field-based research.

3.8 Acknowledgements

We gratefully acknowledge NSERC, Stillwater Canada Inc. and the China Scholarship for funding this project. John McBride, Katrina McLean and Ryan Ruthart of Stillwater Canada are particularly thanked for their help with field work. Additional support for pXRF analyses was provided by Elemental Controls Ltd. and for bSEM analyses by JEOL. The manuscript was improved by constructive reviews by S. Piercey and G. Hall.

4.1 Introduction

Geochemical analysis of drill core is an essential component of mineral exploration. Conventional lab-based geochemical analyses have high accuracy and precision, but the time needed to obtain results means that decisions cannot be made in the field, in a short time frame. Recent advances in technologies have resulted in a number of field portable analytical techniques that are designed to collect data with minimum time delay and at low cost, which facilitates rapid decision making in the field. Thus, the mineral exploration industry is increasingly using field-portable instruments in modern mineral exploration programs. Portable X-ray fluorescence (pXRF) and benchtop scanning electron microscopy equipped with energy dispersive spectroscopy (bSEM-EDS) are two analytical instruments that can collect rapid lithogeochemical and mineral chemical data in the field.

On-site pXRF lithogeochemical data have been used in mineral exploration applications for some years. For example, Houlihan et al. (2003) presented three cases studies at different Ni, Cu, and Cu-Au mines in Australia, wherein pXRF was evaluated for its ability to be used on-site for ore grade control, and Fisher et al.

(2014) developed a workflow for the collection of pXRF data in an exploration or mining setting. A thorough review of applications of pXRF to mineral exploration is provided by Hall et al. (2011). In contrast to pXRF, applications of bSEM-EDS are still new to mineral exploration. The bSEM-EDS can easily sit on a table in a field setting and can analyze field samples such as rock samples and saw cut blocks without polishing and carbon-coating, which enables the collection of images and EDS mineral chemical analyses at the sub-micron scale as described in chapter 2. Therefore, the bSEM-EDS has great potential for mineral exploration in a manner that is analogous to pXRF. Integrating lithogeochemical and mineral chemical analyses will result in a more comprehensive understanding of geology and mineralogy. The purpose of the current study is to evaluate whether pXRF and bSEM-EDS can be combined as a robust tool to increase the efficiency of both mineral exploration and academic research.

In Chapter 3, we used samples from a single drill hole from the Four Dams area of the Coldwell Alkaline Complex to evaluate the quality of mineral and whole-rock chemical data obtained using bSEM-EDS and pXRF, respectively. Mineral analyses included Mg# data of olivine and clinopyroxene (molar $\text{Mg}/(\text{Mg}+\text{Fe}) \times 100$), and the anorthite content of plagioclase (molar $\text{Ca}/(\text{Ca}+\text{Na}) \times 100$). It was demonstrated that both portable instruments were able to provide analyses comparable to their lab-based counterparts, acquired from electron microprobe and ICP-AES/MS/IR. Similar data quality from pXRF was also reported previously by Hall et al. (2014), Piercey and Devine (2014), and Ross et al. (2014). But the work in chapter 2 was the first study to apply bSEM-EDS to mineral exploration research. The proof of concept study in Chapter 3 is expanded in the current work. The Eastern Gabbro of the Coldwell Alkaline Complex was selected as a case study of combining pXRF and bSEM-EDS for Cu-Pd exploration at a regional scale. Data from around the intrusion are used to evaluate whether field portable techniques can

be used to produce lithogeochemical and mineral chemical sections that can be applied to mineral exploration.

4.2 Geological setting

The Proterozoic Coldwell Alkaline Complex is a sub-circular intrusion that has a diameter of approximately 25 km and a surface area of 580 km² and is the largest alkaline intrusive complex in North America (Walker et al., 1993; Shaw, 1997). It intruded the Archean Shreiber-Hemlo greenstone belt along the northern edge of the Midcontinent rift at 1108-1094 Ma, which marked the beginning of the early stage of magmatism related to the Midcontinent system (Walker et al., 1993; Heaman et al., 2007; Good et al., 2015). Petrologic and field studies conducted by Puskas (1970), Mitchell and Platt (1978, 1982), Mitchell et al. (1993), and Shaw (1997) recognized three superimposed intrusive centers constituting this complex, from east to west, they are center I, center II, and center III (Fig. 4-1). Paleomagnetic work conducted by Ashley and Kerns (2012) suggests that Centers I and III are the same age but both are older than Center II. Center I forms the eastern margin of the Coldwell Alkaline Complex, and is composed by the Eastern Gabbro, the Western Gabbro, amphibole quartz syenite, iron-rich augite syenite, and mafic volcanic and subvolcanic rocks (Walker et al., 1993; Shaw, 1994; Good et al., 2015). Center II consists of alkali gabbro and syenite (Mitchell and Platt, 1978, 1982; Mulja, 1989). Center III is mainly composed of syenite and quartz syenite which are intrusive into most other phases of the complex and exhibit various degrees of crustal contamination (McLaughlin and Mitchell, 1989). It was proposed by Mitchell and Platt (1977, 1978) and Walker et al. (1993) that the emplacement of most rock units in the Coldwell Alkaline Complex was controlled by the faulting during cauldron subsidence at a subvolcanic depth.

According the previous studies of Shaw (1994, 1997), the Eastern Gabbro formed by multiple intrusions of basaltic magma with a subalkaline parentage into a partial ring dike structure that cut the Archean country rock. Good et al. (2015) identified

nine major lithologies that were further grouped into three major distinctive magmatic series. From oldest to youngest, they are the meta-basalt (equivalent to fine-grained gabbro in Good et al., 2015), the Layered Series, and the Marathon Series. The relative ages for these units were established from crosscutting relationships, particularly within the numerous units of igneous breccia (Good et al., 2015). The meta-basalt occurs along the base of the Eastern Gabbro and comprises picritic basalt that underwent pyroxene-hornfels grade metamorphism (Good et al., 2015). The Layered Series constitutes the bulk of the Eastern gabbro and is composed of massive to modally layered olivine gabbro, with a lesser amount of weakly layered oxide augite melatroctolite, and, less commonly, gabbroic anorthosite. The Marathon Series is the youngest unit and comprises numerous small intrusions composed predominantly of ophitic gabbro, apatitic clinopyroxenite, oxide melatroctolite, as well as small volumes of augite troctolite and wehrilite (Good et al., 2015).

A significant problem for mineral exploration in the Coldwell Alkaline Complex is that some phases of the Marathon Series and Layered Series can be difficult to distinguish in the field. However, most of the copper and all of the known PGE mineralization is hosted by the Marathon Series, particularly within an ophitic gabbro that is similar to the Two Duck Lake gabbro at the Marathon deposit, the largest Cu-Pd deposit of the Coldwell Alkaline Complex. By contrast, the meta-basalt and the Layered Series lack significant PGE mineralization. The latter locally hosts disseminated chalcopyrite and pyrrhotite mineralization, but is associated with albite-actinolite alteration, with only trace PGE (<0.005 ppm Pd plus Pt) (see Chapter 3). Therefore, being able to distinguish the entire suite of Marathon Series from other Eastern Gabbro rocks is critical for mineral exploration, particularly if it is possible to differentiate these units in the field.

In Chapter 3, we distinguished the Layered and Marathon Series using field portable techniques at one location, namely the Four Dams location (Fig. 4-1). The purpose

of this contribution is to evaluate whether the methods used in that study can be applied to the Coldwell Alkaline Complex as a whole. To accomplish this, two additional areas were selected: Area 41 and the WD zone (Fig. 4-1), and these are compared with the data from Four Dams. Area 41 is approximately 17 km northwest of the Marathon Cu-Pd deposit. The mineralization is hosted mainly by an ophitic, pegmatitic gabbro, with a small amount occurring within apatitic clinopyroxenite, this will be fully described in Chapter 6. The spatial distributions of different series of rock units at Area 41 are depicted in Figure 4-2. The Four Dams area is approximately 2.5 km north of the Marathon deposit. In contrast to Area 41, the Cu-Pd mineralization at Four Dams area is hosted mainly by an apatitic clinopyroxenite, and only a small amount of the ophitic gabbro unit outcrops in this area (see Chapter 3). The WD zone is located roughly 4 km south of the Marathon deposit. The Cu-Pd mineralization in the WD zone has a lower grade than that in Area 41 or Four Dams (unpublished Stillwater Canada Inc. exploration assay), and the mineralization is mainly hosted by an ophitic gabbro. These three mineralized areas were chosen, not only because they are spatially distributed through most of the length of the Eastern Gabbro, but also because they represent all recognized types of PGE mineralization in the Eastern Gabbro (cf. Good et al., 2015; Chapter 6).

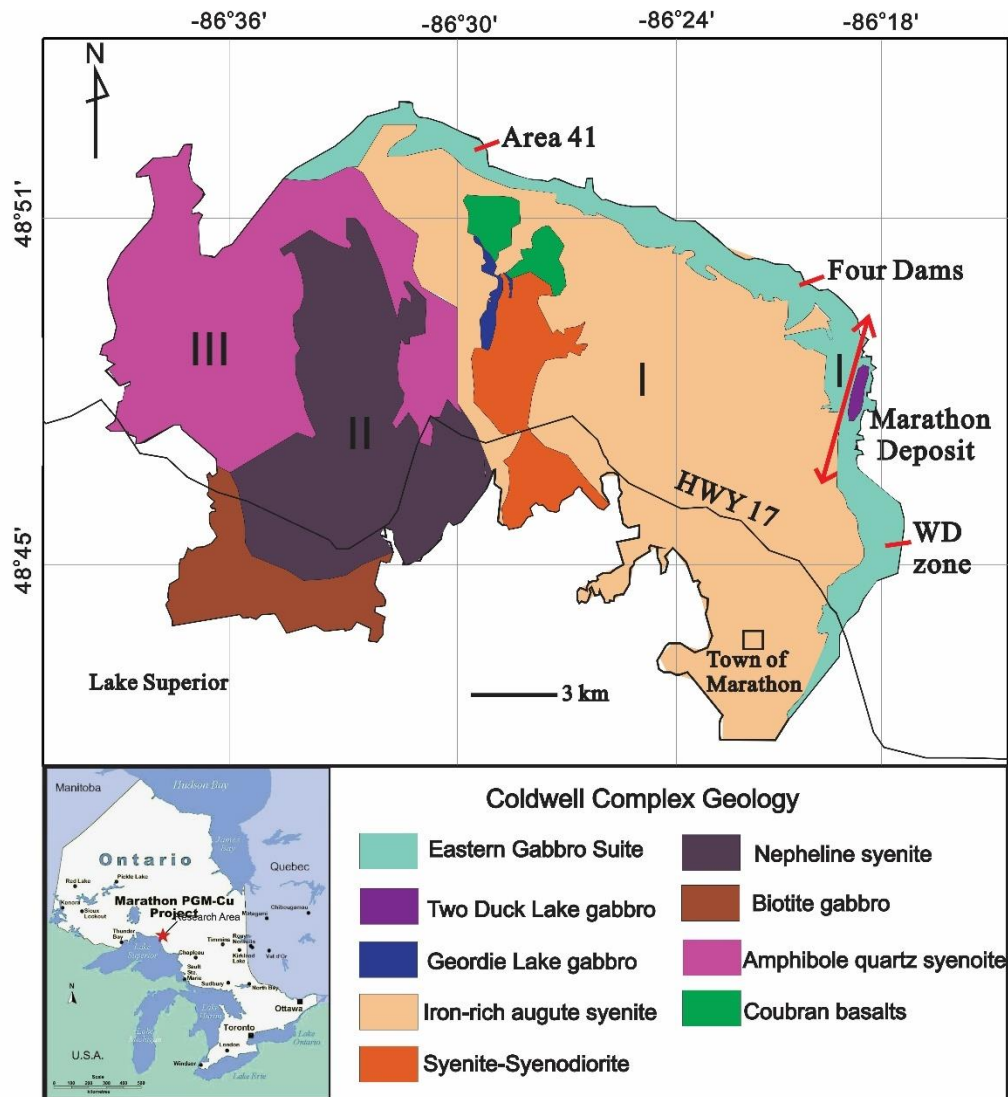

Figure 4-1. Geological map of the Coldwell alkaline complex, situated on the northern shore of Lake Superior. Locations of Area 41, Four Dams, and WD zone are represented as red dots (Simplified after Walker et al., 1993 and Good et al., 2015). The intrusive centers have been shown by Roman numerals (modified after Mulja and Mitchell, 1991). The location of the Marathon deposit is indicated using a double arrowed red line.

Figure 4-2. Igneous stratigraphy of Area 41 mineralization area. The columns represent the geological log of each of the drill holes, black lines indicate geological contacts.

4.3 Methods

4.3.1 Sample preparation

Powders and rock specimens were obtained from representative diamond drill holes at Area 41 (SL-13-32, SL-13-34, SL-13-37, SL-13-41), Four Dams (FD-13-34), and the WD zone (MW-07-06). All these drill holes intersect a sequence of the Layered Series and the Marathon Series rocks; their drilling parameters are tabulated in Table 4-1.

Table 4-1. Drilling parameters of sampled diamond drill holes (DDH).

Area	DDH Number	Azimuth	Collar	Total Depth (m)
Area 41	SL-13-32	20	-85	252
	SL-13-34	19.56	-80	201
	SL-13-37	20.42	-80	261
	SL-13-41	18.36	-80.05	291
Four Dams	FD-13-34	32.9	-69.6	375
WD zone	MW-07-06	89	-60	168

A total of 283 powdered samples were collected by grinding 1 m-long channels at regular intervals along the length of the drill core, approximately 2 mm wide and 1 cm deep, using a Thermo Scientific portable grinder. Sampling protocols have been described in Chapter 2. Sample locations for powdered samples are given in Figure 4-3. After grinding, powders were loaded into PREM-4331 XRF sample cups capped with 4- μ m PREM-F2540 XRF sample cup film for pXRF analyses. A subset of representative powder samples was further pulverized and sent for lab-based analyses.

A total of 149 polished thin sections, representative of different series' gabbro units with different styles of mineralization (e.g., chalcopyrite-rich, and pyrrhotite-rich), were prepared for petrographic and mineral chemical studies. The interval between mineralogical samples was 5 to 20 meters; the locations of polished thin section samples are given in Figure 4-3. Note that although polished thin sections were used in this study, in Chapter 3 we demonstrated that analyses could also be obtained from cut blocks. A comparison of results from cut blocks (unpolished and polished) and polished thin sections is provided below, in section 4.3.2.2.

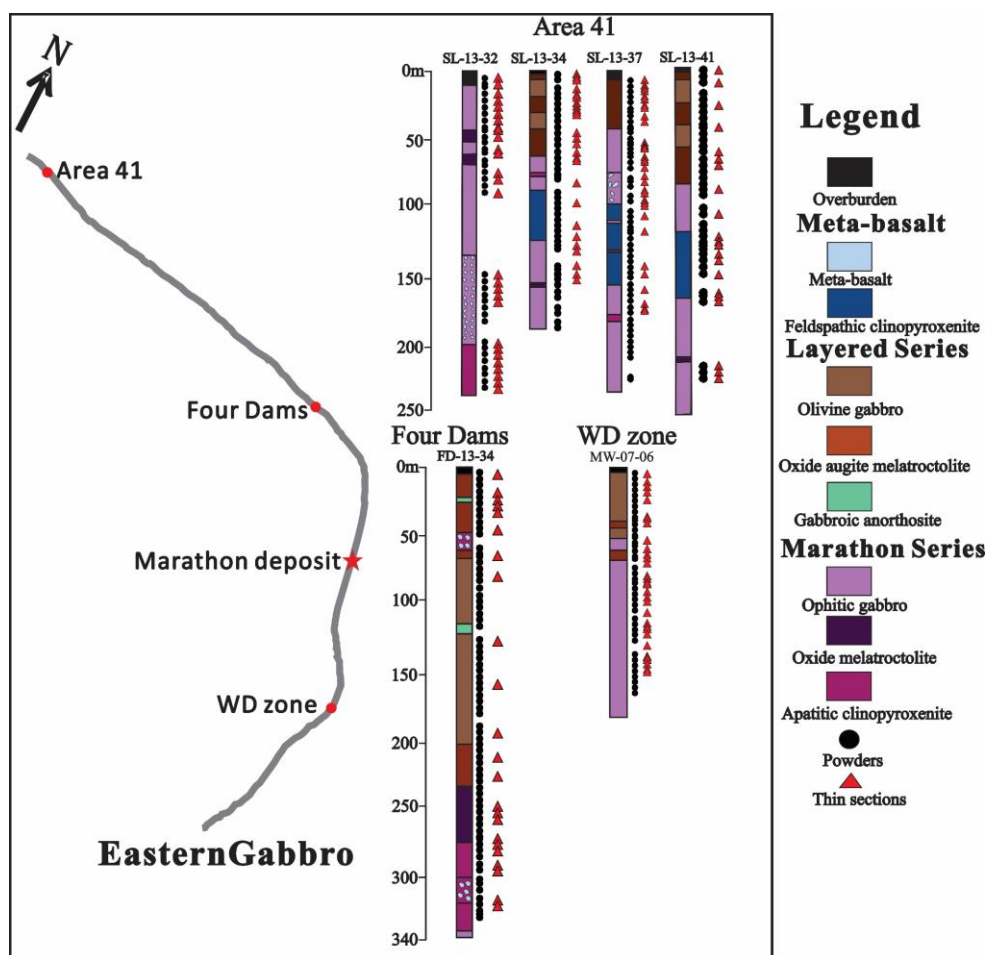

Figure 4-3. Sample locations for powders (circles) and thin sections (triangles) from six representative diamond drill holes: FD-13-34 at Four Dams (see Chapter 3), SL-13-32, SL-13-34, SL-13-37 and SL-13-41 at Area 41, and MW-07-06 at the WD zone. The columns represent the geological log of each of the drill holes. The outer contact of the Eastern Gabbro is represented by the thick grey line and different studied areas are outlined using three red dots. The location of the Marathon Cu-Pd deposit is also indicated by a red star.

4.3.2 Analytical equipment

4.3.2.1 Whole-rock analyses

A NitonXL3t+ GOLDD+ pXRF analyzer equipped with a SDD, and a high energy, 50Kv X-ray Ag anode tube was used to analyze powdered samples. Details of analytical strategies and QA/QC control are given in Chapter 3. The analytical error for pXRF analysis with 95% confidence (2σ) was determined through duplicate analyses conducted on the same sample. pXRF results with analytical errors for elements of interests (Cu, S, Zr, Ba, V, Ti) can be found in Appendix 5. Conventional lithogeochemical analyses were conducted on selected re-ground

samples by ALS Mineral Division in Vancouver. Major elements were analyzed by lithium borate fusion with inductively coupled plasma (ICP)-atomic emission spectroscopy (AES) on a minimum 2 g of pulp samples. Trace elements were analyzed by lithium borate fusion and ICP-mass spectroscopy (MS) on 2 g of pulp samples. Total S was determined using a Leco combustion furnace on 0.01 to 0.1 g of sample, in which the sample is heated to roughly 1350°C in an induction furnace. SO₂ is produced through a reaction with oxygen and is measured by an infra-red detector. Quality control was achieved using ALS geochemical quality-control procedures which involve analyses on a wide array of standards, blanks, and duplicates after each batch of samples. Conventional lithogeochemical results with 95% confidence (2σ standard deviation) are given in Table 4-2.

Table 4-2. Selected lab-based whole-rock Ba, Zr, Cu, S, V, Ti concentrations based on ICP-MS analyses, and ratios of V/Ti and Cu/S in this study. 95% confidence error for element is given in the bracket. Error for the ratio represents 95% confidence error calculated based on the equation $\sigma_{(A/B)} = A/B \times ((\sigma_A/A)^2 + (\sigma_B/B)^2)^{1/2}$

Drill hole	Depth	Elements (ppm)						Ratios			
		Ba (43.5)	Zr (10.4)	Cu (10.3)	S (60)	V (17.5)	Ti (180)	V/Ti	Error	Cu/S	Error

4.3.2.2 Mineral chemical analyses

Major constituents of olivine, clinopyroxene, and plagioclase were acquired on a JEOL JCM-6000 NeoScope SEM (bSEM) equipped with a JEOL JED-2300 energy-dispersive X-ray analyser at Western University. Analyses were conducted on all prepared carbon-coated polished thin sections using 15 keV accelerating voltage, a high beam current, a 19 mm working distance, a 30-40 μm beam size, and standardless ZAF corrections. The analytical precision of bSEM-EDS analyses has been determined in Chapter 3 by analyzing the same spot 10 times: results are ± 0.51 for Mg# of olivine, ± 1.0 for Mg# of clinopyroxene, and ± 0.63 for anorthite content

of plagioclase (1σ standard deviation). The analytical precision (machine error), combining with the nature variation, constitute the sample variability determined through bSEM-EDS analyses on 3-5 grains of each mineral type in each sample (see Appendix 7). A subset of representative carbon-coated polished thin sections was chosen for electron microprobe analyses, conducted using a JEOL JXA-8530F field-emission probe at Western University. Major and minor constituents of olivine, plagioclase, clinopyroxene were measured. Operating conditions comprised an accelerating voltage of 15 keV and a beam current of 20 nA. The beam was focused to a 1 μm spot for analyzing olivine and clinopyroxene, and to a 5 μm spot for analyzing plagioclase. The peak counting time was 30 s for all elements and background counts were a total of 30 s. A variety of synthetic and natural standards were used to calibrate different elements during probe analyses (Table 4-3). The precision of electron microprobe analyses was determined in Chapter 3 to be ± 0.07 for Mg# of olivine, ± 0.30 for Mg# of clinopyroxene, and ± 0.15 for plagioclase anorthite content (1σ standard deviation), determined by analysis of the same spot 10 times. These values (machine errors) are significantly lower than those for EDS analyses, and are also well below the sample variabilities which were determined through bSEM-EDS analyses conducted on 3-5 grains of each mineral type (Table 4-4).

Figure 4-4 compares bSEM-EDS analytical results and images for a sample prepared in three ways: unpolished cut thin section block, polished cut thin section block, and (carbon-coated) polished thin section. It shows that analytical results from both the unpolished block and polished block are close to those from the polished thin section, and that the polishing process for the block improved the results to some extent. BSE images and EDS mapping for all three sample preparations are similar in terms of identifying minerals and textures, although the rough surface is evident on the BSE image from the unpolished block.

Scan image	Average analyses	BSE image	EDS mapping
 <p>Unpolished block</p>	<p>Mg# of Ol=73.1 Mg# of Cpx=77.2 An% of Pl=44.3</p>		
 <p>Polished block</p>	<p>Mg# of Ol=64.5 Mg# of Cpx=75.2 An% of Pl=44.5</p>		
 <p>Thin section</p>	<p>Mg# of Ol=58.9 Mg# of Cpx=72.7 An% of Pl=43.3</p>		

Figure 4-4. Comparison of EDS results, BSE images, and EDS mappings from a same sample (SL-13-37-80) in three different formats: unpolished cut thin section block, polished cut thin section block, and (carbon-coated) thin section. The white square denotes the location for BSE image. Abbreviations: Pl-plagioclase, Mt-magnetite, Ilm-ilmenite.

Table 4-3. Standards used for electron microprobe analyses of olivine, clinopyroxene, and plagioclase.

Olivine and Clinopyroxene		Plagioclase	
Element	Standard	Element	Standard

4.4 Lithology

Representative hand sample pictures for units as described below are shown in Figure 4-5. Note how similar appearances among these units, particularly to oxide augite melatroctolite and oxide melatroctolite.

4.4.1 *Meta-basalt*

The meta-basalt occurs along the base of the Eastern Gabbro and makes up approximately one quarter to a third of the total Eastern Gabbro package (Good et al., 2015, note that meta-basalt is equivalent to the fine-grained series described in this reference). This unit was intruded by the later Marathon Series intrusions such as an ophitic gabbro, and occurs locally as xenoliths within the Marathon Series rocks. Its composition varies from basalt to olivine basalt, and consists of equigranular, fine-grained subhedral clinopyroxene, olivine, and magnetite, with interstitial plagioclase. The meta-basalt is distinguished by its recrystallized

granoblastic texture (120° boundaries between crystals, Fig. 4-6A), reflecting the pyroxene hornfels-grade metamorphism, likely caused by heat from later intrusions.

4.4.2 Feldspathic clinopyroxenite

The feldspathic clinopyroxenite is exposed at Area 41, and is not observed at Four Dams or the WD zone. McBride (2013) suggested that the feldspathic clinopyroxenite is an older intrusion that is potentially related to the meta-basalt based on crosscutting relationships and mineral textures. The mineralogy of the feldspathic clinopyroxenite, in decreasing order of abundances, comprises medium- to coarse- grained clinopyroxene (60-80 modal%), olivine (5-15 modal%), plagioclase (5-10 modal%), magnetite (less than 5 modal%), and trace disseminated sulfide minerals that are dominated by pyrrhotite and chalcopyrite. Plagioclase occurs either as coarse-grained subhedral grains interstitial to cumulate olivine and clinopyroxene, or as rounded, fine-grained inclusions enclosed by clinopyroxene. Magnetite and sulfide minerals typically occur as inclusions within olivine and clinopyroxene. The feldspathic clinopyroxenite is moderately to extensively altered, as reflected by a network of chlorite stringers (Fig. 4-6B).

4.4.3 Layered Series

The Layered Series makes up most of the Eastern Gabbro, and has a consistent intergranular texture and mineralogy throughout. It is dominated by massive to modally layered olivine gabbro and weakly layered oxide augite melatroctolite, with lesser amounts of gabbroic anorthosite. As will be shown in Chapter 5, the olivine gabbro and the oxide augite melatroctolite represent compositional end-members of the same unit, with similar concentrations of high field strength elements (HFSE) and mineral chemistry.

4.4.3.1 Olivine gabbro

The olivine gabbro is medium- to coarse- grained (1-4 mm). Layering of this unit is defined by a gradational change in the abundance of plagioclase (Fig. 4-7A), or by the alternation of plagioclase-rich and clinopyroxene-rich sublayers. It consists of euhedral plagioclase (40-60 modal%), subhedral clinopyroxene (15-30 modal%),

subhedral olivine (10-15 modal%), less than 10 modal % apatite plus magnetite, and less than 5 modal % subhedral biotite and/or anhedral alkali feldspar. Locally, plagioclase grains occur as chadocrysts enclosed by olivine and clinopyroxene oikocrysts, and olivine is rimmed by clinopyroxene, indicating a plagioclase-olivine-clinopyroxene crystallization sequence (from early to late). Minor phases such as apatite, magnetite, and biotite typically occur interstitial to olivine and plagioclase. Alkali feldspar (perthite) is only observed in olivine gabbro at Area 41 and the WD zone (Fig. 4-6C), whereas it is negligible in olivine gabbro at Four Dams.

4.4.3.2 Oxide augite melatroctolite

The oxide augite melatroctolite is medium grained and has textures that are similar to olivine gabbro. It displays weak modal layering and is distinguished from other units by a greater abundance (10 to 20 modal %) of disseminated magnetite. The mineralogy of this unit is similar in the different areas, in decreasing order of abundance, olivine (20-45 modal%), plagioclase (15-30 modal%), clinopyroxene (10-20 modal%), magnetite, and apatite (<10 modal%). Olivine and clinopyroxene are euhedral, and occur interstitial to subhedral to anhedral plagioclase clusters. Magnetite and apatite are generally enclosed by, or are less commonly interstitial to olivine and plagioclase.

4.4.3.3 Gabbroic anorthosite

The gabbroic anorthosite is older than the Layered Series gabbro because it typically occurs as meter-sized xenoliths throughout the Layered Series olivine gabbro (Good et al., 2015). This unit has a very distinctive mottled appearance and consists of approximately 80 modal % medium-grained, subhedral to anhedral plagioclase, very coarse-grained clinopyroxene (10 modal %) and olivine (5 modal %) oikocrysts, and 5 modal % medium- to coarse-grained, interstitial to poikilitic magnetite.

4.4.4 Marathon Series

4.4.4.1 Ophitic gabbro

The ophitic gabbro is medium-grained (<2 mm) to pegmatitic (>4 mm). It has a characteristic ophitic to subophitic texture that resembles the Two Duck Lake gabbro at the Marathon deposit (Fig. 4-7B). Minerals present are, in approximately decreasing order of abundance, subhedral plagioclase (40-70 modal%), subhedral clinopyroxene (15-30 modal%), euhedral to subhedral olivine (5-10 modal%), and less than 10 modal% magnetite and apatite. This unit constitutes the majority of the Marathon Series, and is the main host of Cu-Pd mineralization, at both Area 41 and the WD zone. However, at Four Dams, only a small amount of ophitic gabbro is present. At Area 41, the ophitic gabbro can be further subdivided into three subtypes based on differences in grain size (Fig. 4-2), namely medium-grained ophitic gabbro, coarse-grained ophitic gabbro, and pegmatitic gabbro, more details can be seen in Chapter 6. The medium-grained ophitic gabbro contains negligible olivine, and PGE mineralization is mainly hosted by the coarse-grained and pegmatitic ophitic gabbro. There is some local development of secondary minerals such as chlorite, amphibole, serpentine, and calcite particularly in the pegmatitic ophitic gabbro.

4.4.4.2 Apatitic (olivine) clinopyroxenite

The apatitic (olivine) clinopyroxenite is an apatite-rich rock which consists of up to 30 modal % apatite (Fig. 4-6D). Other minerals present are medium- to coarse-grained subhedral clinopyroxene (30-60 modal%) and olivine (10-20 modal%), subhedral plagioclase (5-10 modal%), and less than 10 modal% magnetite and biotite. At Four Dams, this unit is the main Marathon Series rock, and hosts the majority of Cu-Pd mineralization, in contrast to Area 41 and the WD zone. At Area 41 (and possibly the WD zone), the apatitic (olivine) clinopyroxenite constitutes a minor proportion of the Marathon Series and typically occurs as thin lenses within the ophitic gabbro. Moderate to strong chlorite and actinolite alteration is commonly observed in this unit.

4.4.4.3 Oxide melatroctolite

The oxide melatroctolite occurs as pods that typically are located within the main body of the ophitic gabbro at Area 41 and the WD zone. As described in Chapter 3, in the Four Dams area, this unit sits below the oxide augite melatroctolite, and constitutes an important Marker Horizon that indicates the transition from the PGE-barren Layered Series to the PGE-mineralized Marathon Series. Similar to the Layered Series oxide augite melatroctolite, the oxide melatroctolite also contains a greater abundance of subhedral magnetite (40-60 modal %). This unit also contains olivine, clinopyroxene, plagioclase (the total amount of the three minerals generally is less than 30 modal %), and from 2 to 30 modal % euhedral apatite.

4.4.5 Breccia

Breccias within the Marathon Series generally comprise either an ophitic gabbro matrix with angular xenoliths of meta-basalt or footwall rocks, or an apatite clinopyroxenite-dominated matrix with meta-basalt or footwall xenoliths. At Four Dams, breccia also cuts the Layered Series, and consists of meta-basalt rocks that were cut by multiple thin dikelets of the Marathon Series gabbro. Similar breccia rocks were observed by Good et al. (2015) at the Marathon deposit. It should be noted that these breccia rocks contain sulfide-bearing ophitic gabbro and apatitic clinopyroxenite, which are also important hosts to Cu-PGE mineralization, particularly at Area 41.

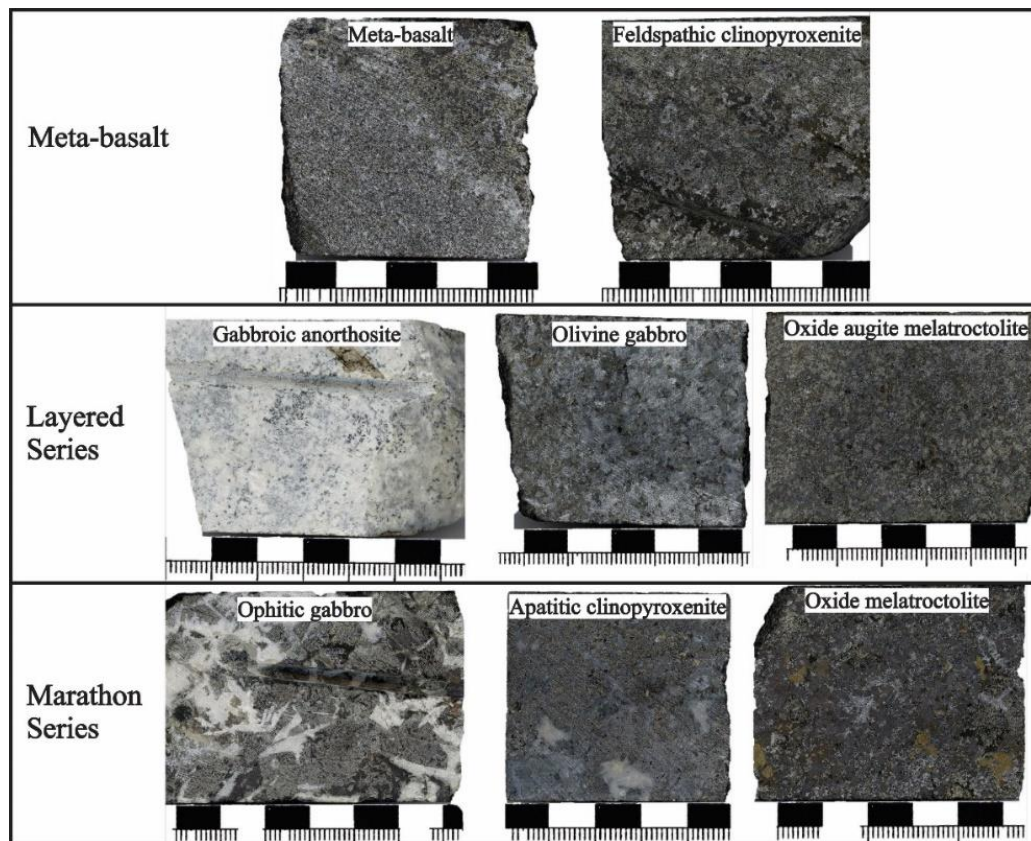

Figure 4-5. Representative hand sample pictures for different units at the Eastern Gabbro.

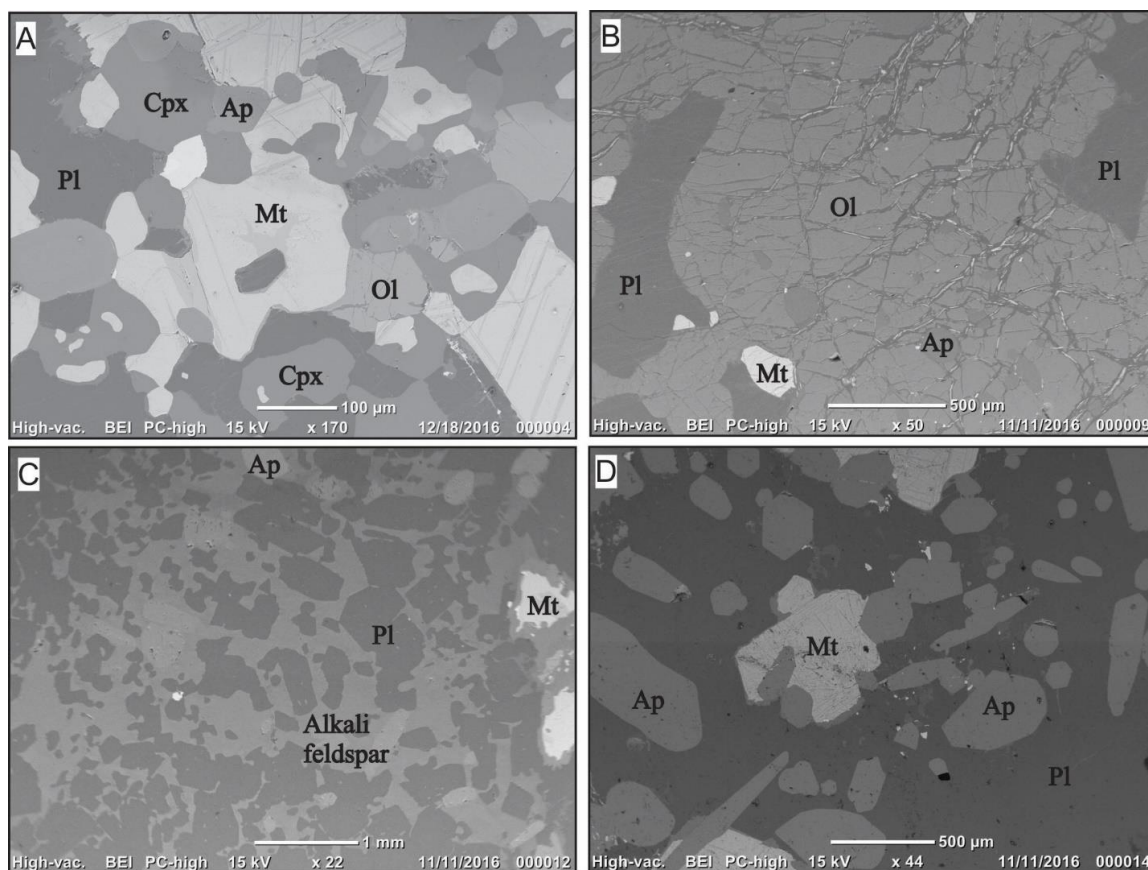

Figure 4-6. BSE images showing mineral compositions and textures for various units. (A) The recrystallized texture in the meta-basalt, note the nearly 120° angles of boundaries between different crystals; (B) The net-work chlorite stingers crosscutting the Ol crystal in feldspathic clinopyroxenite; (C) Alkali feldspar surrounds euhedral-subhedral Pl in the olivine gabbro at Area 41; (D) Many Ap inclusions in plagioclase, as observed in apatitic clinopyroxenite. Abbreviations: Ol-olivine, Cpx-clinopyroxene, Pl-plagioclase, Mt-magnetite, Ap-apatite.

Figure 4-7. Outcrops for the Layered Series units and the Marathon Series ophitic gabbro. (A) The layering reflects a gradational change in the abundance of plagioclase; (B) The ophitic gabbro; note the typical ophitic texture for gabbro along the upper part of the photo and the finer grained xenolith beneath the lens cap.

4.5 Validation of results from portable techniques

Since the accuracy and precision of data collected by field portable analytical instruments are inevitably poorer than those of lab-based analyses, the quality of the data should be assessed prior to real-time measurements.

4.5.1 *pXRF*

pXRF analyses of Ba, Zr, Cu, S, V, Ti, Cu/S, and V/Ti are compared to their lab-based counterparts in Figure 4-8. Coefficients of determination (R^2) between pXRF and ICP-AES/ICP-MS/IR are above 0.8 for all elements and ratios, indicating excellent correlations for results between these two different methods. Therefore, when down-hole variations of these elements and ratios are of particular interest, pXRF analyses will generate comparable profiles to their lab-based counterparts. Moreover, the high accuracy of pXRF Zr, V, Ti, and V/Ti data are reflected by data distributions that fall close to the 1:1 line with lab-based data. By contrast, pXRF data accuracy for Ba, Cu, S, and Cu/S are poorer. However, since there are excellent correlations between pXRF and lab-based Ba, Cu, S, and Cu/S, recalibration can be applied to improve data accuracy, as shown in Chapter 3.

4.5.2 *bSEM-EDS*

On Figure 4-9, bSEM-EDS analyses of the Mg#s of olivine and clinopyroxene, and the anorthite content of plagioclase are compared to microprobe analyses, with both sets of analyses on the same grains. The correlation between data from the two methods are excellent for the Mg# of olivine ($R^2=0.92$) and the anorthite content of plagioclase ($R^2=0.86$), and reasonable for the Mg# of clinopyroxene ($R^2=0.73$), similar to the comparison made in Chapter 3. Therefore, down-hole variations in these parameters from bSEM-EDS analyses are comparable to their probe counterparts.

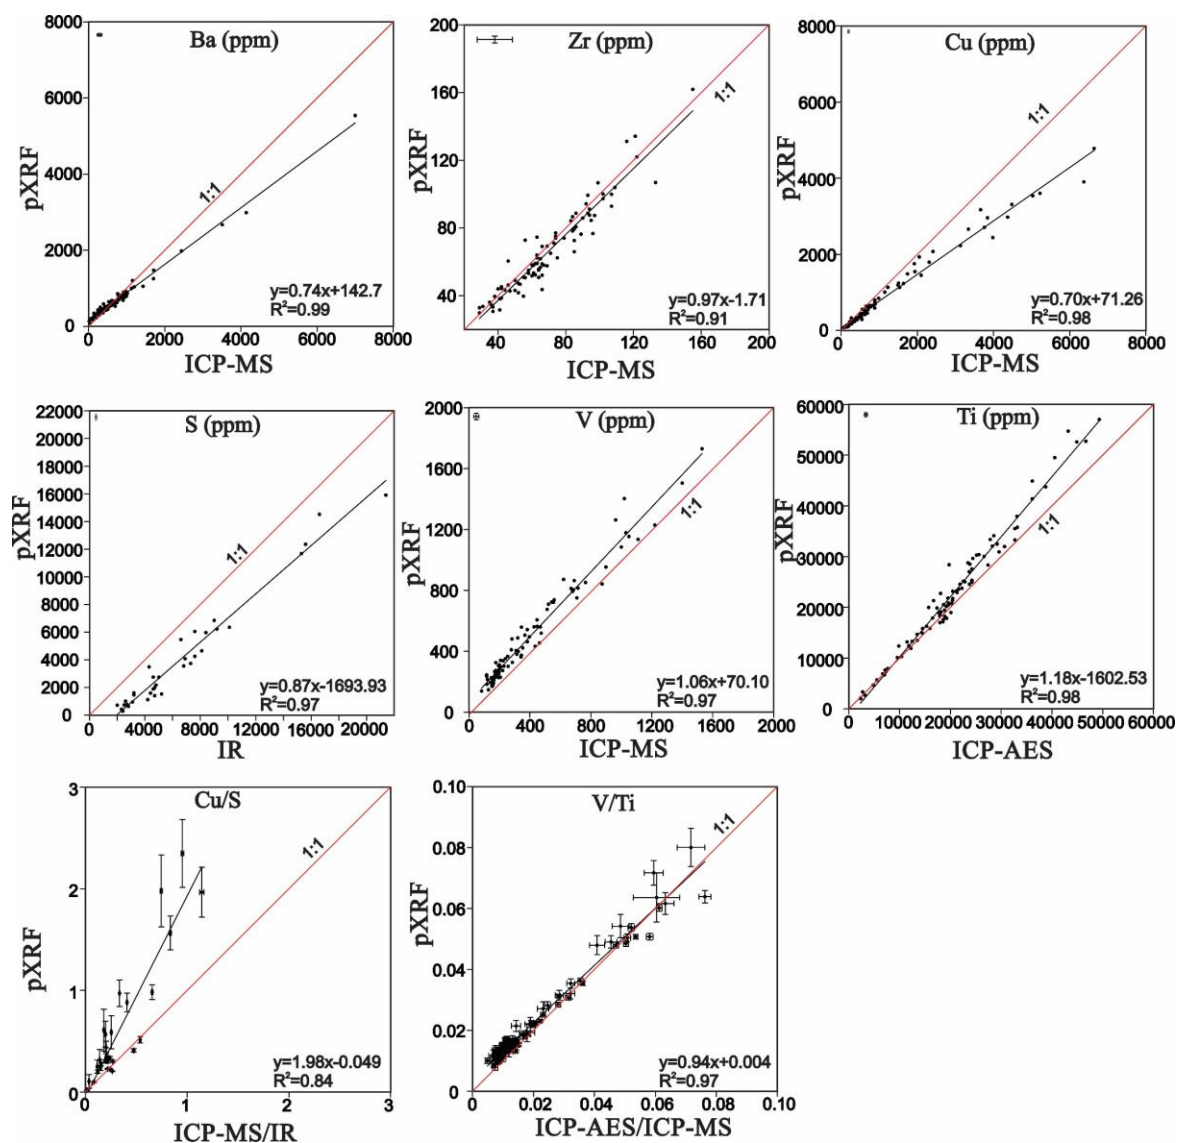

Figure 4-8. Comparisons between pXRF analyses and ICP-AES/ICP-MS/IR analyses. Error bar represents 95% confidence (2σ standard deviation) of analytical uncertainty determined by repetitive analyses.

Figure 4-9. Binary diagrams correlating bSEM-EDS analyses with microprobe analyses. Error bars represents 1 σ sample errors determined through EDS analyses conducted on 3 or 4 grains of each mineral type in each sample, and multiple spot analyses were conducted on each mineral grain. Average values are correlated in this figure.

4.6 Results

4.6.1 Whole-rock compositions

Concentrations of pXRF whole-rock Ba, Zr, and V/Ti ratios in Layered Series and Marathon Series units at the three locations are summarized in Figure 4-10. Generally, the Layered Series units contain higher Ba and Zr contents than the Marathon Series units. This is particularly evident by comparing various rock units from the same area. In addition, the Layered Series units from the WD zone and Area 41 contain higher Ba contents than those from Four Dams, and there is an increase in Zr contents for the Layered Series units from Area 41, through Four Dams, to the WD zone. V/Ti ratios for the Layered Series units from all three localities are lower than 0.025, whereas those for the Marathon Series units generally are above 0.03, up to around 0.09 for the apatitic clinopyroxenite at Four Dams.

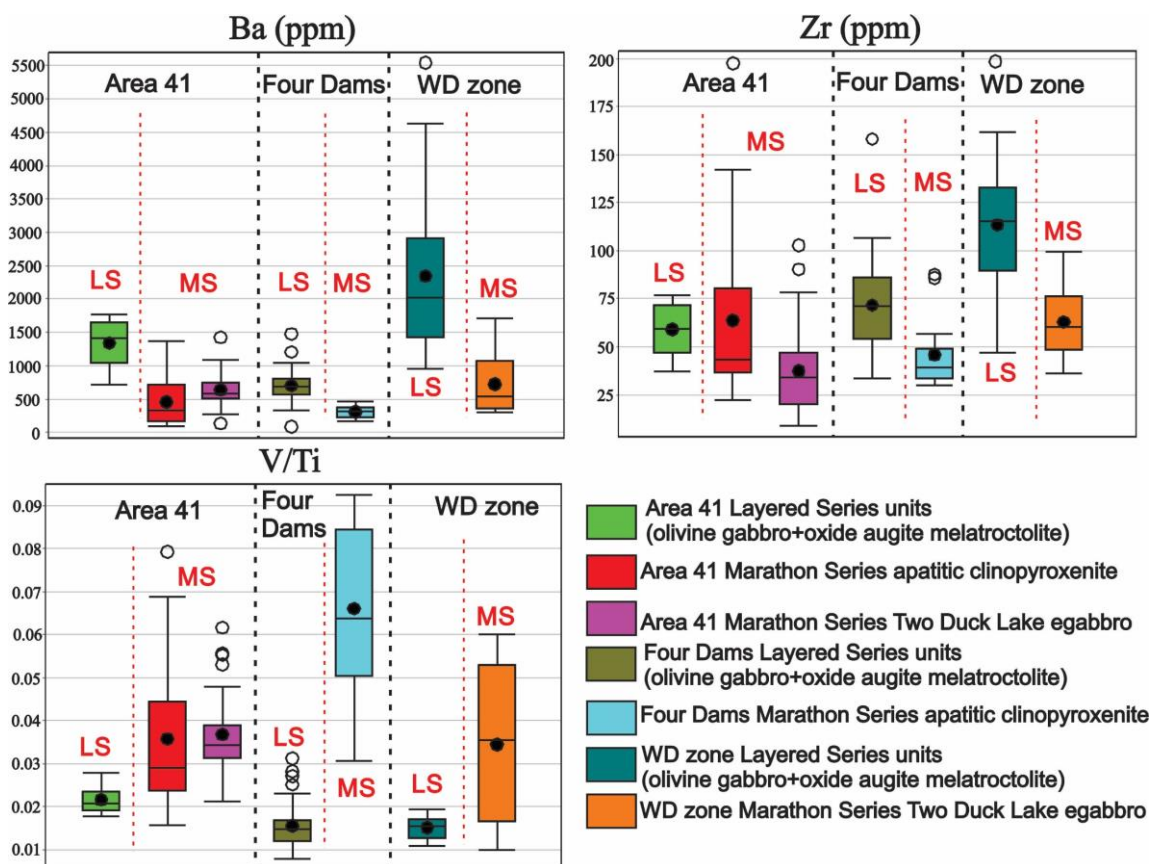

Figure 4-10. Box and whisker plots for selected trace elements in different rock units of different localities. Box and whisker plots are uniform in their use of the box: the bottom and top of the box are always the 25th and 75th percentile (the lower and upper quartiles, respectively), and the band near the middle of the box is always the 50th percentile (the median). The small black infilled circle is the average and the lines on the ends are the minimum and maximum values, black empty circles are outliers.

4.6.2 Mineral chemical compositions

The Mg#s of olivine and clinopyroxene, and the anorthite content of plagioclase determined by bSEM-EDS for Layered Series and Marathon Series units are summarized in Figure 4-11. Generally, the Marathon Series units have higher Mg#s of olivine and clinopyroxene, and anorthite content of plagioclase than the Layered Series rocks, particularly when comparing rock units of the same area. Interestingly, at Area 41 the apatitic clinopyroxenite has higher Mg# values but lower anorthite content of plagioclase than the Layered Series gabbro, this may indicate that the plagioclase was an entrapped phase in this unit, or reflect the great uptake of Ca by apatite and clinopyroxene. The Layered Series units and the Marathon Series ophitic

gabbro at the WD zone have lower Mg#s of olivine and clinopyroxene, and anorthite content of plagioclase, respectively, than the Area 41 and Four Dams Layered Series and Marathon Series units.

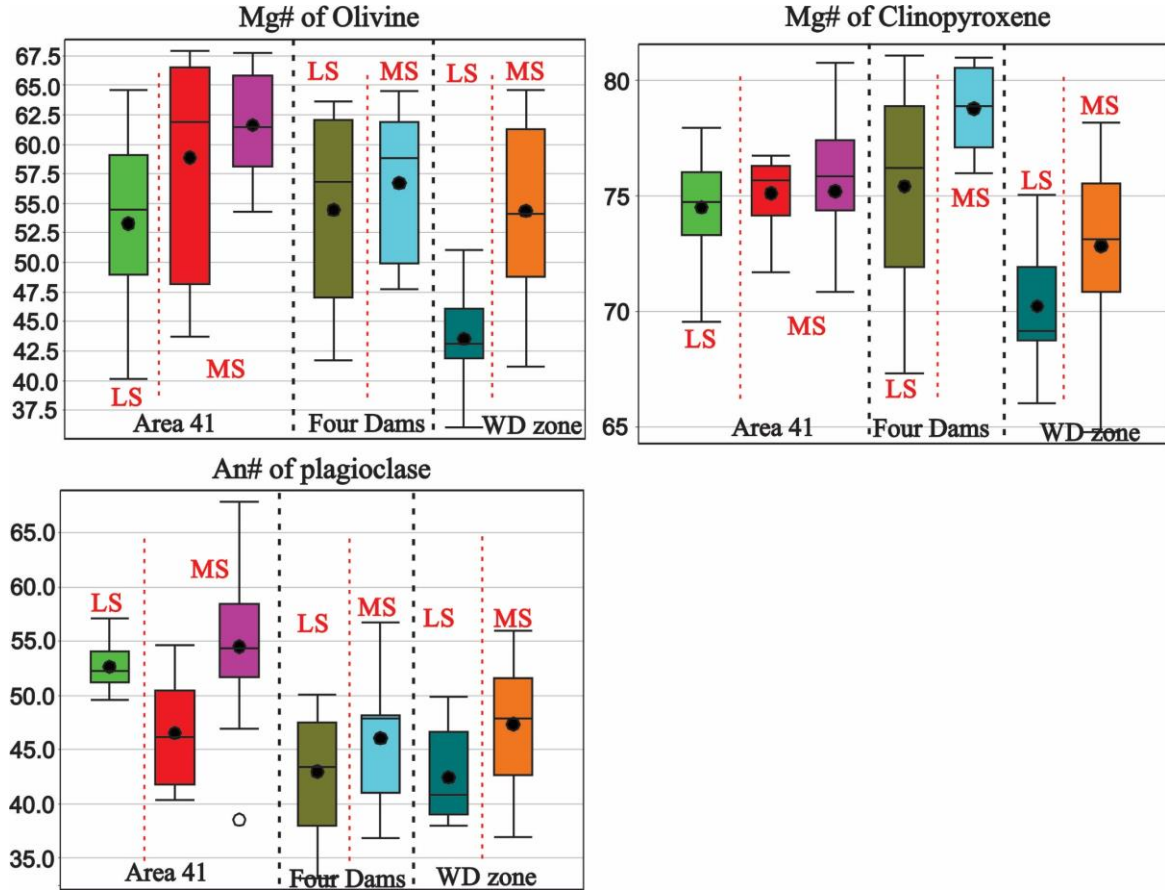

Figure 4-11. Box and whisker plots for mineral chemical compositions in different rock units of different localities, legends as in Figure 4-10.

4.6.3 Down-hole profiles

Down-hole geochemical profiles of Cu/S (pXRF-based and/or lab-based), pXRF Ba, pXRF V/Ti, pXRF Zr, and the bSEM-EDS Mg#s of olivine and clinopyroxene for three representative drill holes (SL-13-37, FD-13-34, MW-07-06) at Area 41, Four Dams, and WD zone are displayed in Figures 4-12, 4-13, and 4-14. Note that three PGE mineralized zones (defined by >100 ppb Pd plus Pt) are outlined in the three figures. Based on unpublished exploration assay data, the mineralized zone in SL-13-37 and FD-13-34 contain higher PGE grades than the that in MW-07-06 (430 ppm Pt and 630 ppm Pd on average for SL-13-37, 1690 ppb Pd and 800 ppb Pt on

average for FD-13-34, and 150 ppm Pt and 390 ppm Pd on average for MW-07-06). Seven significant characteristics of these down-hole profiles are:

- 1) the Layered Series units at Area 41 and the WD zone generally present down-hole decreases in Ba and Zr, and down-hole increases in V/Ti and the Mg#s of olivine and clinopyroxene;
- 2) the Layered Series at Four Dams does not show much variation in Ba and V/Ti with depth, but is characterized by a general down-hole increase in Zr and decrease in the Mg#s of olivine and clinopyroxene;
- 3) the Marathon Series, by contrast, lacks any consistent down-hole variations in these variables, and instead is characterized by fluctuations of these parameters in the ophitic gabbro at Area 41 and the WD zone;
- 4) the apatitic clinopyroxenite at Four Dams has a general down-hole decrease in Zr, and increase in V/Ti and the Mg#s of olivine and clinopyroxene, but all these variables also show zig-zag patterns;
- 5) it is apparent that the Layered Series units in the three areas have higher Ba and Zr, and lower V/Ti ratios than their Marathon Series counterparts;
- 6) Rock units within the PGE mineralized zones in the shown drill holes contain significantly higher Cu/S ratios than other rock units;
- 7) in SL-13-37, for the Marathon Series ophitic gabbro that contains PGE mineralization, the Mg#s of olivine and clinopyroxene are significantly more variable than the Layered Series units, as well as the rest of PGE-poor Marathon Series rocks. Note that other drill holes (see Appendix 5 & 7) exhibit similar characteristics as those illustrated above.

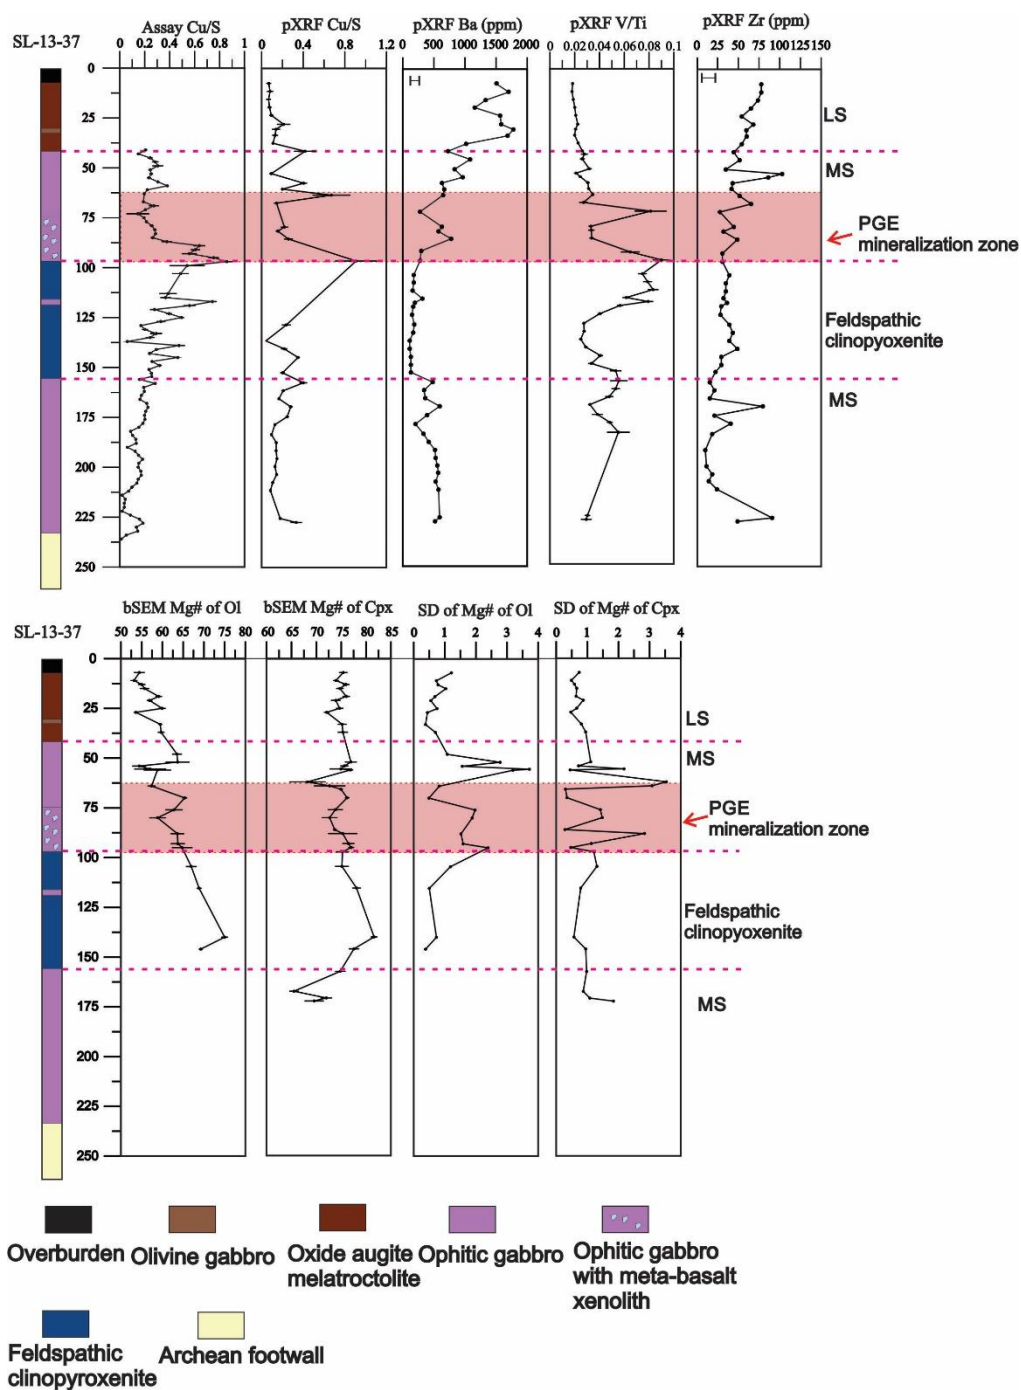

Figure 4-12. Geochemical profiles down the drill hole SL-13-37 at Area 41, the shaded area indicates the PGE mineralization zone. The error bar for pXRF analysis represents 2σ analytical uncertainty determined by multiple analyses on the same powder. The error bar for bSEM-EDS analysis represents 1σ sample variability determined by 3-5 analyses on 3-5 grains of each mineral type in each sample. SD means 1 sigma standard deviation.

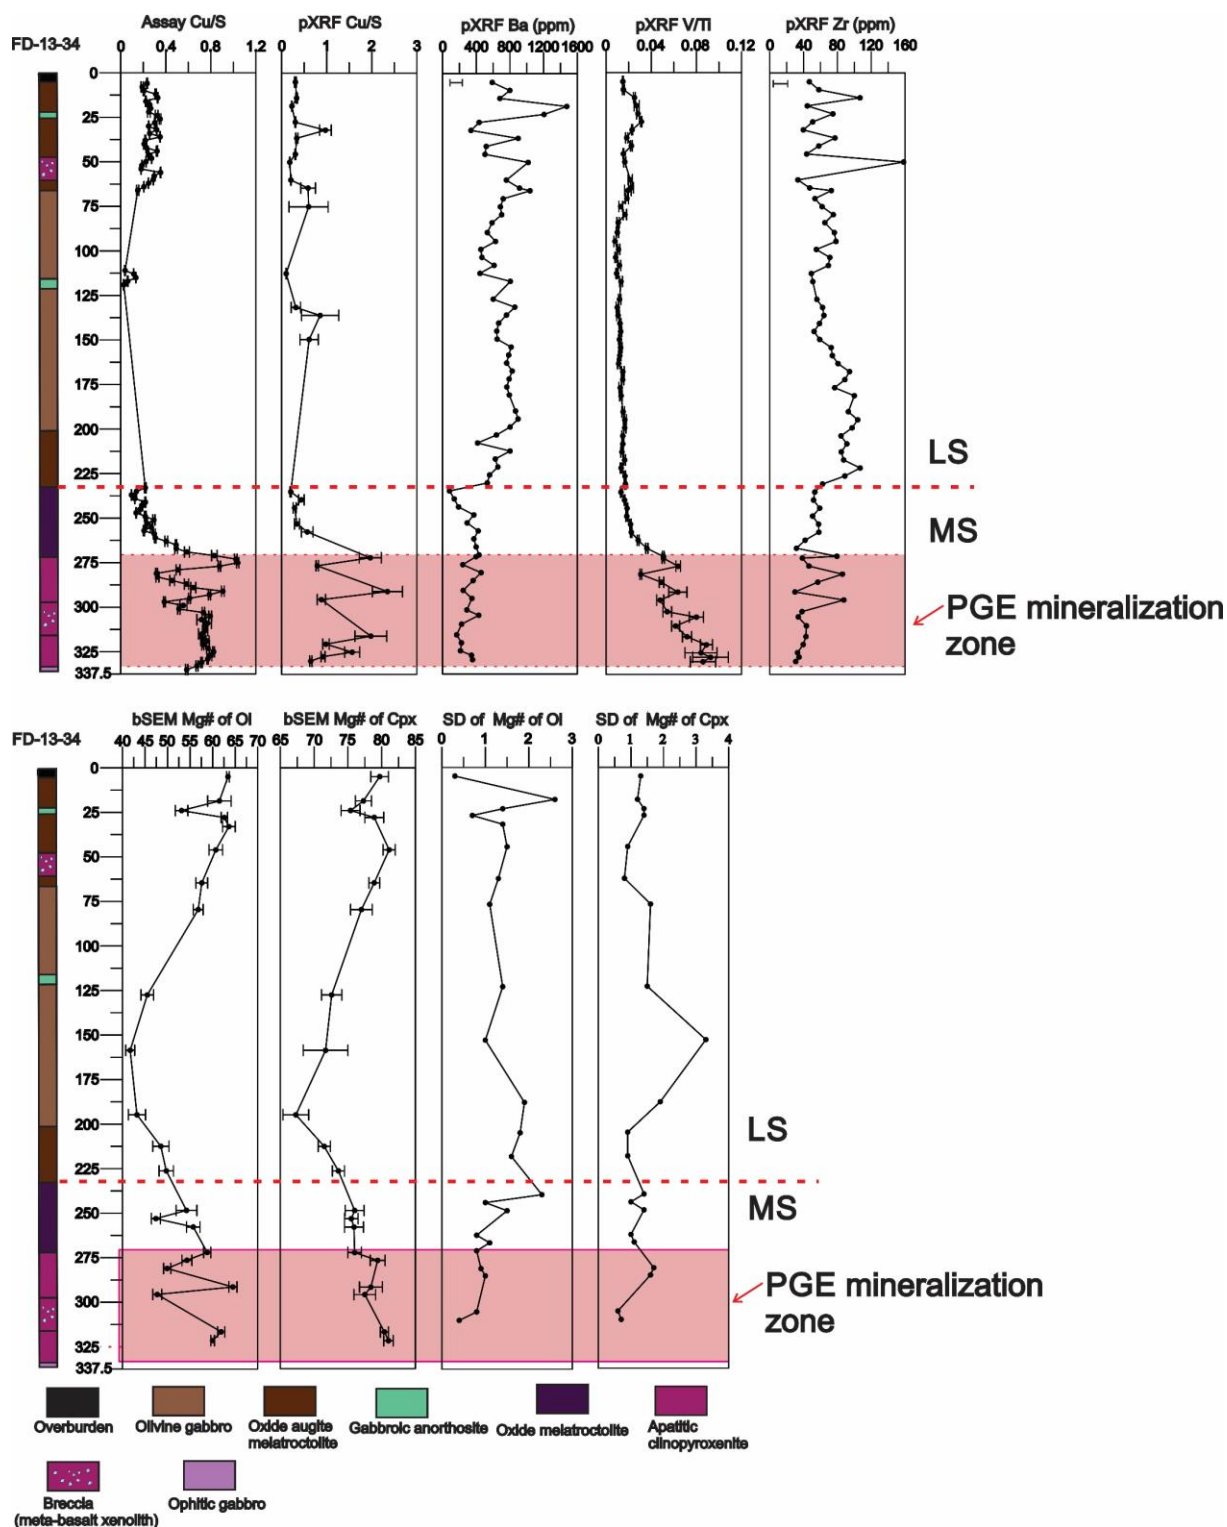

Figure 4-13. Geochemical profiles down the drill hole FD-13-34 at Four Dams, the shaded area indicates the PGE mineralization zone. The error bar for pXRF analysis represents 2σ analytical uncertainty determined by multiple analyses on the same powder. The error bar for bSEM-EDS analysis represents 1σ sample variability determined by 3-5 analyses on 3-5 grains of each mineral type in each sample. SD means 1 sigma standard deviation.

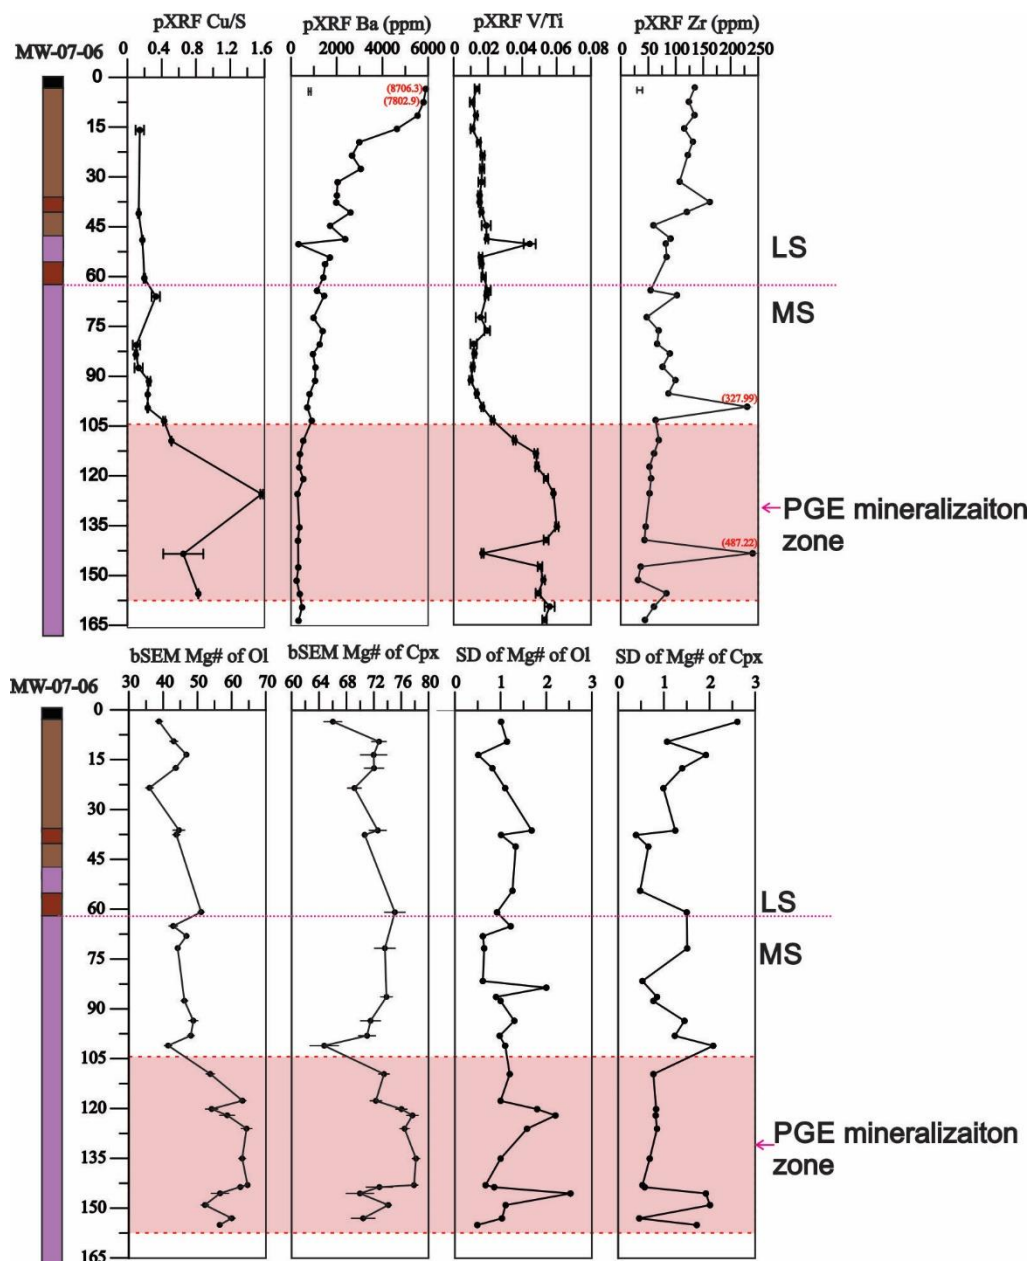

Figure 4-14. Geochemical profiles down the drill hole MW-07-06 at WD zone, the shaded area indicates the PGE mineralization zone, other legends as in Figure 4-12. The error bar for pXRF analysis represents 2σ analytical uncertainty determined by multiple analyses on the same powder. The error bar for bSEM-EDS analysis represents 1σ sample variability determined by 3-5 analyses on 3-5 grains of each mineral type in each sample. SD means 1 sigma standard deviation.

4.7 Discussion

4.7.1 Cu/S proxy

In Chapter 3, we identified two zones of sulfide mineralization located at the top and bottom of drill hole FD-13-34 using both exploration assay and pXRF data. The

upper zone (within the Layered Series and lacking PGE mineralization) is characterized by low Cu/S ratios, whereas the lower zone (within the Marathon Series and containing PGE mineralization) is characterized by high Cu/S ratios. It was thus suggested that high Cu/S ratios could serve as a proxy for PGE mineralization in the Four Dams area. In this study, within the PGE mineralized zones of Area 41, Four Dams, and the WD zone, Cu/S ratios are significantly elevated, indicating that high Cu/S seems to be a good proxy for PGE mineralization in all three areas. Both Cu and S can be acquired by pXRF, although the detection limit for S is normally high in most pXRF instruments; Hall et al. (2011) determined a S detection limit of around 300 ppm using five types of pXRF instrument. As long as Cu and S are detected by pXRF, their ratios are comparable to lab-based methods (Fig. 4-8). Therefore, although pXRF is unable to detect PGE due to the high detection limit relative to the PGE concentrations in most geological materials, it still can be used to vector towards potential PGE mineralization in the Eastern Gabbro by determining Cu/S ratios in the field.

Using the high Cu/S proxy as an exploration tool may also be applicable to other PGE-dominated deposits. Platinum-group elements, particularly Pd and Pt, tend to preferentially partition into the Cu-rich residual liquid after monosulfide solid solution (MSS) crystallization (Howell and McDonald, 2010). Provided that the magmatic sulfide liquids fractionated MSS, Pd and Pt would be concentrated in areas where Cu-rich sulfide minerals, such as chalcopyrite, cubanite, and bornite, are abundant, all of which have high Cu/S ratios. Barnes and Ripley (2016) also suggested that the Cu-rich ores are normally enriched in Pd and Pt. Notable examples include the PGE-enriched sulfide horizons at the Dunka Road Cu-Ni-PGE deposit at the Duluth Complex, which are typically composed of intergrown chalcopyrite, cubanite, and pentlandite, with less abundant pyrrhotite (Theriault et al., 1997), and the Platinova Reef in the Skaergaard Intrusion where magmatic sulfide minerals are present as a Cu-rich, Fe-poor assemblage (Nilsen, 2001).

4.7.2 Identification of possible magma recharge zones

Magma recharge is favorable for PGE mineralization because: 1) it implies the existence of a magma conduit setting, whereby PGE mineralization can be controlled by various fluid dynamic processes (Marsh, 2006); and, 2) the sulfide tenor can be gradually upgraded through a magma recharge process (Kerr and Leitch, 2005), thus increasing the potential for discovery of high-grade deposits. The work in Chapter 3 identified possible recharge zones within the PGE mineralized zone at Four Dams using the combination of pXRF and bSEM-EDS. The criteria used include the zig-zag down-hole variations in pXRF whole-rock MgO and the bSEM-EDS Mg# of olivine (reproduced in Figure 4-13), and the replacement of early plagioclase by later more calcic plagioclase. Figures 4-12 and 4-14 show that in the Marathon Series ophitic gabbro units in Area 41 and WD zone drill holes, particularly those within the PGE mineralized zone, the Mg#s of olivine and clinopyroxene fluctuates over short distances (Figs. 4-12 and 4-14), consistent with a magma recharge process that involves multiple intrusions. Furthermore, the more variable Mg#s of olivine and clinopyroxene for the ophitic gabbro units within the mineralized zone of SL-13-37 from Area 41 (Table 4-4, Fig. 4-12) imply a dynamic environment, which is consistent with a magma recharge environment. Note that brecciated rocks are observed in drill hole SL-13-37 (Fig. 4-12), which is a good indicative of recharge near magma conduits. By contrast, the PGE mineralized ophitic gabbro units in MW-07-06 from the WD zone exhibit a relatively small variation in the Mg#s of olivine and clinopyroxene, suggesting a less dynamic setting. Considering that the PGE mineralization in MW-07-06 has a lower grade than that in SL-13-37, differences in PGE grade may be related to differences in variations of Mg# values, i.e., greater variation corresponds to a higher PGE grade. However, the apatitic clinopyroxenite in FD-13-34 from Four Dams, which contains a higher grade of PGE mineralization than the WD zone, also contains olivine and clinopyroxene that exhibit a small variation in their Mg# values. Therefore, the

greater variability of Mg# as a potential vector to higher PGE grades perhaps is only applicable to the ophitic gabbro that contains PGE mineralization, rather than the apatitic clinopyroxenite. Nevertheless, an initial impression of PGE mineralization can be gained through investigating the variability in mineral chemistry, particularly for the ophitic gabbro, by using bSEM-EDS prior to traditional assays, which can take weeks or more to complete.

Magma recharge zones may also be related to the replacement of early, less-calcic plagioclase by later more-calcic plagioclase (Fig. 4-15). This texture is observed in mineralized zones in SL-13-37, MW-07-06, as well as in FD-13-34 as described in Chapter 3. Similar textures were also observed by Good and Crocket (1994) and Shahabi Far (2016) in the Marathon deposit, where it was interpreted to reflect multiple intrusions. It is notable that the later plagioclase occurs intergrown with sulfide minerals that show close associations with PGM grains (Fig. 4-15). This was interpreted by Shahabi Far (2016) as the presence of sulfide liquid when late-stage hydrous melt/hydrous fluid replaced the early formed plagioclase. Therefore, using the bSEM-EDS to identify magma recharge zones is another exploration tool that seems well suited to the entire Eastern Gabbro, and may also be applicable to PGE deposits in other settings since magma conduits are a common factor favorable for PGE mineralization (Naldrett, 1999).

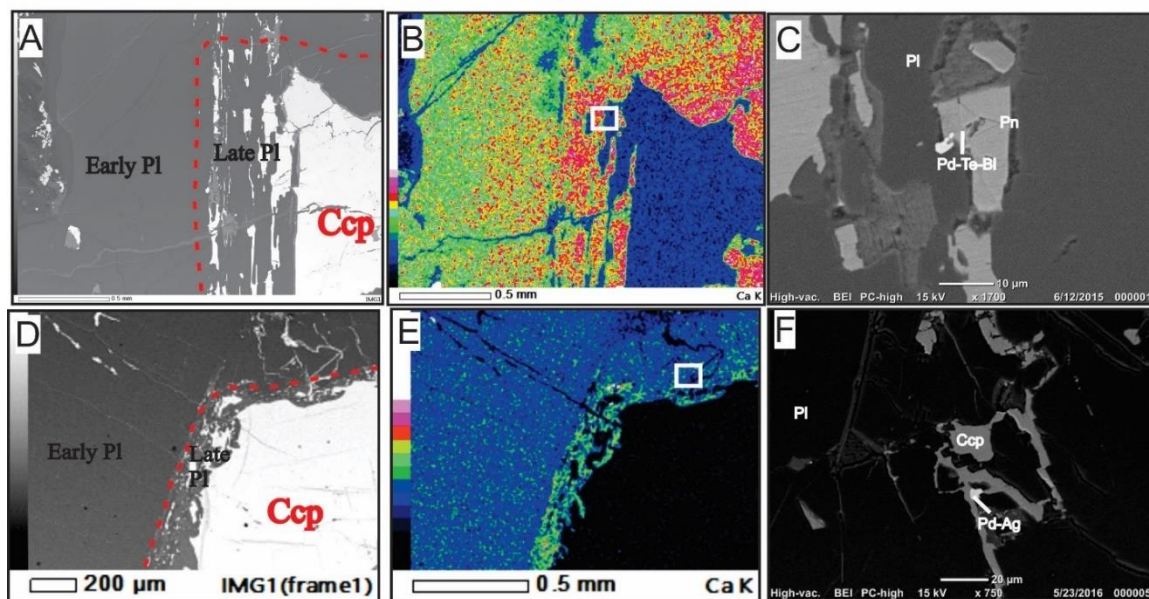

Figure 4-15. Possible magma recharge evidence as reflected by the replacement of earlier less calcic Pl by later more calcic Pl, the later plagioclase occurs intergrown with Ccp. PGM grains are observed in the intergrown Ccp. (A)-(C) are for the ophitic gabbro within the mineralization zone of SL-13-37, note that white particles on (A) and (B) are actually small grains of carbonates; (D)-(F) are for the ophitic gabbro within the mineralization zone of MW-07-06. The white unfilled boxes indicate locations where PGM grains were observed. Abbreviations: Ccp-chalcopyrite, Pn-pentlandite, Pl-plagioclase, Ol-olivine.

4.7.3 Discrimination of the Layered and Marathon Series

As mentioned above, successfully identifying the Marathon series units from the Layered Series units, particularly in the field, will help increase mineral exploration success. However, a challenge is that some Marathon Series rocks are petrographically similar to some Layered Series rocks (Fig. 4-4). Lab-based results of Good et al. (2015) show that the two series are geochemically distinctive, and can be discriminated in diagrams of Ce vs. Y and Nb vs. Zr. Zirconium is an element that can be measured by pXRF, but Ce, Y, and Nb in geological materials are normally below detection. This means that these two discrimination diagrams are not suited to the field-based approach. Additional discrimination diagrams using data from field-portable instruments therefore need to be developed.

Our pXRF results show that Ba and V/Ti in the Layered Series are significantly different from those in the Marathon Series. The Layered Series units have higher

Ba and lower V/Ti than the Marathon Series units. Shaw (1997) relate differences in Ba between these two series to the greater abundance of Ba-rich biotite and orthoclase in the Layered Series, consistent with the interpretation in Chapter 3. The lower V/Ti ratio of the Layered Series may indicate that it is more evolved than the Marathon Series, because down-hole V/Ti and mineral compositional profiles in the same holes in Layered Series (Figs. 4-12 and 4-14) suggest that V is more compatible than Ti in this magmatic system, i.e., V has a higher bulk partition coefficient than Ti due to the fractionation of clinopyroxene, magnetite, etc. Therefore, a discrimination diagram using Ba and V/Ti has application to discriminating between the Marathon and Layered Series throughout the Eastern Gabbro (Fig. 4-16). Since both Ba and V/Ti can be acquired by pXRF, this discrimination diagram can be tested directly in the field.

Figure 4-16. Discrimination diagram of Ba vs. V/Ti that separates the Marathon Series from the Layered Series.

4.7.4 Magma differentiation trends

Both pXRF and bSEM results show that the Layered Series units from Area 41 and the WD zone have consistent down-hole variations in Ba, Zr, V/Ti, and Mg#s of olivine and clinopyroxene (Figs. 4-12 and 4-14). These variations suggest a normal

differentiation trend for the Layered Series units at both areas. The Layered Series units at Four Dams also have consistent down-hole variations in these variables, but their variations reflect a reverse differentiation trend (Fig. 4-13). This is consistent with the observation of Shaw (1997), who also observed both normal and reverse differentiation for the Layered Series in the Bamooos and Highway traverses.

The Marathon Series ophitic gabbro units at Area 41 and the WD zone, by contrast, show fluctuations between normal and reverse differentiation. At Four Dams, although the Marathon Series apatitic clinopyroxenite shows an overall normal differentiation trend, variations in key variables (particularly V/Ti, Zr, Mg# of olivine) show zig-zag patterns (Fig. 4-13). Therefore, inspection of down-hole pXRF Ba, Zr, V/Ti, and bSEM-EDS Mg#s of olivine and clinopyroxene variations of drill cores will facilitate the identification of the Marathon Series from the Layered Series, that is, rock units with smooth down-hole variations in these variables more likely are Layered Series units, whereas rock units with fluctuating values in these variables more likely are Marathon Series units. This forms a useful exploration tool that can be used in the field at the Coldwell Alkaline Complex.

4.7.5 Mg-Fe partition between olivine and clinopyroxene

Figure 4-17 shows down-hole trends in the value of olivine-clinopyroxene Fe/Mg partitioning ($K_{\text{Fe/Mg}}^{\text{Ol/Cpx}} = (\text{Fe/Mg})_{\text{Ol}}/(\text{Fe/Mg})_{\text{Cpx}}$, in mole) measured by bSEM-EDS. The Layered Series at Area 41 and WD zone are characterized by a down-hole decrease in this value, whereas the Layered Series at Four Dams shows a down-hole increase in this value; these trends are similar to those determined by microprobe-based mineral chemical analyses, as will be shown in Chapter 5. In contrast, the Marathon Series in all three areas is characterized by small variations in olivine-clinopyroxene Fe/Mg partitioning; this is particularly true for the Marathon Series units within the PGE mineralized zones, where the value of olivine-clinopyroxene Mg/Fe partition is almost constant at a value around 1.8.

The Fe/Mg partitioning between olivine and clinopyroxene in natural basaltic and andesitic magmas was experimentally investigated by Loucks (1996). Provided that olivine and clinopyroxene are in chemical equilibrium, Loucks (1996) found that temperature was a major control on Fe/Mg partitioning between the two minerals. Shahabi Far (2016) estimated a crystallization temperature for the ophitic gabbro at the Marathon deposit of 1400 K, using a clinopyroxene-orthopyroxene geothermometer. At that temperature, the olivine-clinopyroxene Fe/Mg partition coefficient calculated using the equation of Loucks (1996) is around 1.8, close to the measured values for the ophitic gabbro and apatitic clinopyroxenite in this study. By contrast, the measured values for the Layered Series deviate from 1.8, and can increase or decrease with depth, but typically have values >1.8 , ranging up to 4.0. The Marathon Series ophitic gabbro and apatitic clinopyroxenite thus apparently are closer to being in chemical equilibrium compared to the olivine and clinopyroxene in the Layered Series, or the two series formed at different temperatures. This feature also differentiates these two series of rocks. Thus, investigating olivine-clinopyroxene Fe/Mg partition value by using bSEM-EDS in the field potentially can be an exploration tool. Further, it seems that the values closer to chemical equilibrium at 1400 K (1.8) may serve as a vector to PGE mineralization at the Coldwell Alkaline Complex.

The different down-hole patterns and values in olivine-clinopyroxene Fe/Mg partitioning between the Layered Series and the Marathon Series mean that the two series have experienced different histories or conditions during their formation. There are several possible explanations. For example, the trapped liquid shift that results from the back-reaction of residual melt with cumulate minerals may result in disequilibrium between olivine and clinopyroxene (Latypov, 2015). In this case, the non-constant partitioning value for the Layered Series mean that it has undergone variable degrees of trapped liquid shift during its formation. The values for the Marathon Series units that are closer to equilibrium may suggest that the associated

magma has undergone longer re-equilibration between cumulates and residual melts. Another possible explanation is related to undercooling. The undercooling of magma will result in chemical disequilibrium between mineral phases (Latypov, 2015). In this case, the Layered Series seems to have undergone undercooling, whereas the Marathon Series has not. Further assessment of these hypotheses will be addressed in chapter 4 using lab-based analyses.

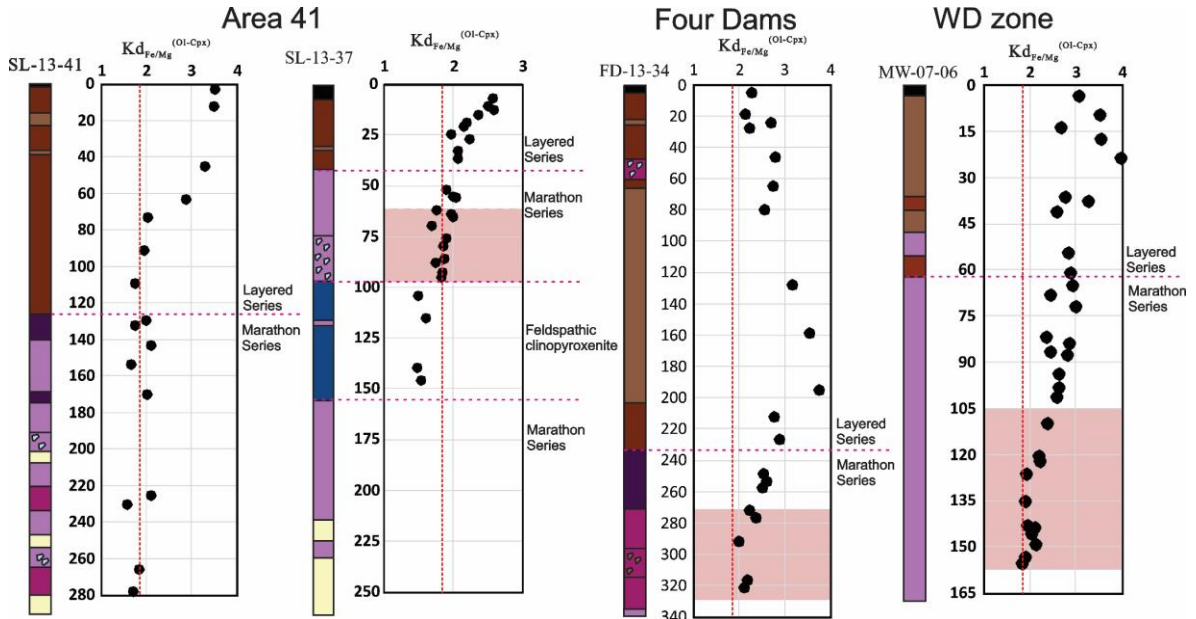

Figure 4-17. Down-hole variations in Fe-Mg exchange coefficient between olivine and clinopyroxene ($Kd_{Fe/Mg}^{Ol/Cpx} = (Fe/Mg)_{Ol}/(Fe/Mg)_{Cpx}$, in mole) for representative drill holes at Area 41, Four Dams, and WD zone. Red vertical dashed lines indicate the olivine-clinopyroxene equilibrium Mg-Fe exchange coefficient (1.8) at 1400 K. Pink boxes indicate the PGE mineralization zones. Legends for units as in Figure 4-2.

4.7.6 Geochemical stratigraphy

Understanding the spatial distribution of different series is of vital significance for mineral exploration in the Eastern Gabbro. In order to enhance exploration success, the establishment of a reliable igneous stratigraphy is needed, which normally requires high quality and quantity of drill core logging and petrographic analysis. The results presented above demonstrate that the combination of pXRF and bSEM-EDS is beneficial for differentiating rock units of the different series. Adopting this concept, a geochemical stratigraphy for Area 41 can be created from pXRF and

bSEM-EDS, and compared to the stratigraphy based on drill core logging (Fig. 4-18). The geochemical stratigraphy is distinctive and is generally in agreement with the igneous stratigraphy from core logging. For instance, the Layered Series generally contains higher K_2O , Ba, and Sr contents than the Marathon Series. The medium-grained ophitic gabbro contains lower P_2O_5 , Fe_2O_3 , higher Al_2O_3 and Sr contents than the coarse-grained and pegmatitic ophitic gabbro. The feldspathic clinopyroxenite and the apatitic clinopyroxenite are also clearly indicated by the geochemical stratigraphy, e.g., low Al_2O_3 , P_2O_5 , K_2O , Ba, Sr abundances and the highest Mg#s of olivine and clinopyroxene for the feldspathic clinopyroxenite, and high CaO and P_2O_5 abundances for the apatitic clinopyroxenite. Therefore, the combination of both portable techniques will provide a robust tool to aid in the interpretation of igneous units directly in the field. This is particularly important when the drill core was logged by several people with different interpretations of the petrographic characteristics of units, and when confirmation is needed to establish a reliable stratigraphy for mineral exploration.

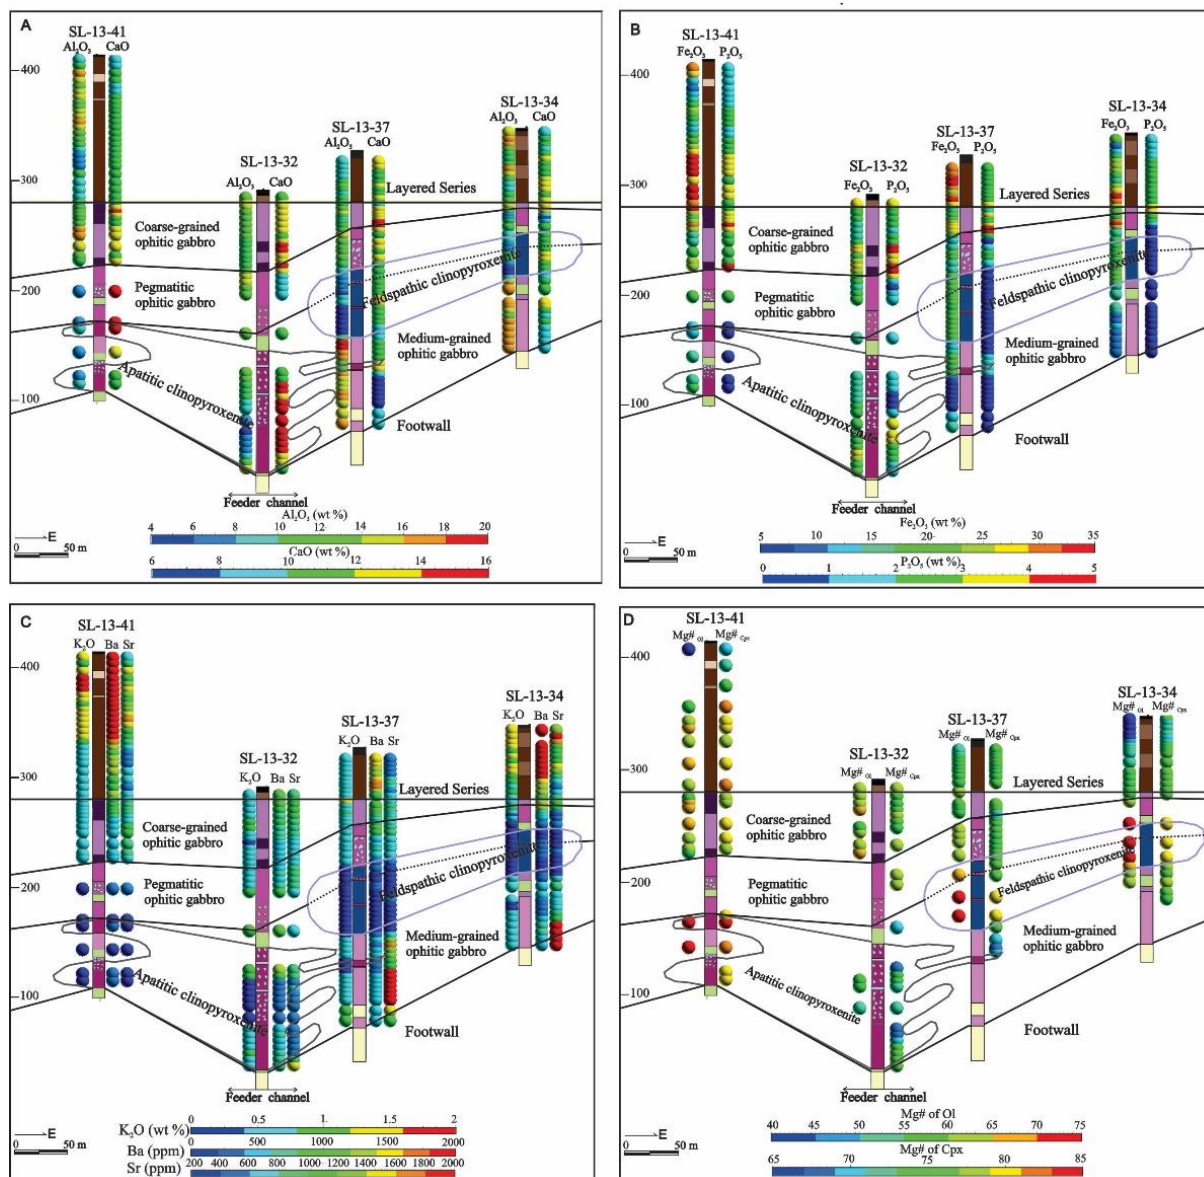

Figure 4-18. Geochemical stratigraphy at Area 41, created based on pXRF Al_2O_3 , CaO , Fe_2O_3 , P_2O_5 , K_2O , Ba, and Sr, and the bSEM-EDS $\text{Mg}^\#$ s of olivine and clinopyroxene. Legends of units as in Figure 4-2.

4.8 Conclusions

The combination of pXRF and bSEM-EDS has considerable promise as an exploration technique for the entire Eastern Gabbro of the Coldwell Alkaline Complex, and has potential to be applied to other PGE deposits in other settings such as the Skaergaard Intrusion:

- (1) pXRF can be used in an indirect way to help exploration through acquiring Cu/S ratios, since high Cu/S ratio can serve as a proxy to PGE mineralization.
- (2) Both pXRF and bSEM-EDS are able to help identify favorable, PGE mineralized magma recharge zones through investigation of down-hole profiles of whole-rock MgO, Mg#s of olivine and clinopyroxene, and sample variabilities of Mg#s of olivine and clinopyroxene, as well as the observation of favorable textures such as the replacement of earlier plagioclase by later more calcic plagioclase.
- (3) The combination of pXRF and bSEM-EDS also provide a reliable tool to help distinguish the Marathon Series from the Layered Series through using whole-rock V/Ti vs. Ba, down-hole profiles of Mg#s of olivine and clinopyroxene.
- (4) The Layered Series units have consistent down-hole variations in the partition coefficient of Fe/Mg between olivine and clinopyroxene. By contrast, the Marathon Series units, particularly for those within the PGE mineralized zone, have almost invariant olivine-clinopyroxene Mg/Fe partition coefficient, which is closer to the equilibrium value at 1400 K. Therefore, the Marathon Series can also be distinguished from the Layered Series by investigating olivine-clinopyroxene Fe/Mg partition coefficient using bSEM-EDS analysis.
- (5) The geochemical stratigraphy created based on pXRF and bSEM-EDS analyses at Area 41 shows an agreement with the drill-log based counterpart, thus the combination of both techniques can assist igneous stratigraphy logging work in a field setting.

1. Western University, London, ON, Canada

2. The University of Windsor, Windsor, ON, Canada

5.1 Introduction

The Coldwell Alkaline Complex, located on the north shore of Lake Superior, is related to the Midcontinent Rift and consists dominantly of gabbros and syenites from three overlapping intrusions (Mitchell and Platt, 1977, 1982). Igneous units associated with this complex have received considerable attention because they potentially contain information on the formation of the Midcontinent rift and the nature of the sub-continental mantle (e.g., Heaman and Machado, 1992).

The Eastern Gabbro forms the oldest intrusive phase in the Coldwell Alkaline Complex. It has received many studies particularly after the discovery of significant Cu-Pd mineralization within a late gabbroic series known as the Two Duck Lake gabbro, *e.g.*, Wilkinson and Colvine (1978), Watkinson et al. (1983), Good and Crocket (1994), Dahl et al. (2001), and Good et al. (2015). The Layered Series gabbro constitutes the main part of the Eastern Gabbro and despite overlying the mineralized Marathon Series, it is interpreted to be older than the Marathon Series. However, owing to the lack of PGE mineralization it has received considerably less scientific scrutiny than the Marathon Series. To our knowledge, Shaw (1997) is the only study that focused on the Layered Series at the Eastern Gabbro. Thus, the

characteristics and the origin of this series are still poorly constrained. However, the origin of the Layered Series is critical for the interpretation of the early magmatic history of the Coldwell Alkaline Complex and for the identification of potential additional PGE resources. There are four main questions about the Layered Series that will be addressed in the current study:

(1) The Coldwell Cu-Pd deposits are hosted by gabbros of the Marathon Series, a group of small irregularly shaped rock suite that were proposed by Good et al. (2015) to have formed in a magma conduit setting. The Layered Series units are much larger and slightly older than the Marathon Series units, and they exhibit significantly different styles of intrusion and crystallization. However, it is unclear how the Layered Series formed and recognition of the role played by common magmatic processes such as Rayleigh fractional crystallization or recharge and tapping fractionation are an important first step to defining the magmatic setting.

(2) The Coubran basalts located in the center of the Coldwell Alkaline Complex was proposed by Cundari (2012) to be co-genetic with the Marathon Series. This basalt is highly evolved with high abundances of incompatible elements. However, the Layered Series units, as will be shown below, contain even higher concentrations of incompatible elements than the Coubran basalts. It is unclear what magma at the Coldwell Alkaline Complex can generate such highly evolved suite of gabbro units and whether it is related to the Coubran basalts. But by developing possible fractional crystallization scenarios to explain the Layered Series, it is possible to gain some insight as to what such an initial magma would have been.

(3) The Layered Series lacks PGE mineralization, in contrast to the Marathon Series. It is unclear whether the PGE-barren nature of the Layered Series is related to the source and is explained by a low degree of partial melting, or whether PGE were depleted during a sulfide melt saturation event.

(4) As first noted by Shaw (1997), the Layered Series commonly exhibits reverse evolution trends. Reverse compositional trends are common in silicate layers in layered intrusions, but their origins have been highly debated (*e.g.*, Gunn, 1966; Irvine, 1980; Lightfoot and Naldrett, 1984; Egorova and Latypov, 2012a, b). The exceptional pristine nature of the Layered Series provides a good opportunity to unravel these unusual compositional trends, which will help better understand mechanisms that occurred in the magma chamber and may also provide new insights into the origin of magma reversal trends in general.

This study presents the results of a comprehensive petrographic, mineral chemistry and geochemical study of the Layered Series rocks including the olivine gabbro and oxide augite melatroctolite units. Geochemical modeling work is used to constrain the magma sources, investigate their genetic relations, and evaluate the intrusion mechanisms for various Layered Series units. In particular, two types of magma reversals characterized by coupled/decoupled mineral and whole-rock compositional trends are studied. These can be explained using a fractionation-mixing model, which in turn can be used to propose the potential processes that took place in the magma chambers that generated the Layered Series.

5.2 Geological setting

The Midcontinent rift-related Coldwell Alkaline Complex is the largest alkaline intrusion in North America (Fig. 5-1). The complex is a sub-circular intrusion that has a diameter of approximately 25 km and a surface area of 580 km² (Walker et al., 1993). It intruded the low-grade metamorphic Archean Schreiber-White River greenstone belt of volcanic and sedimentary rocks at 1108 Ma, which marked the early stage of magmatism of the Midcontinent Rift system (Walker et al., 1993; Heaman et al., 2007). Previous petrological and field studies conducted by Mitchell & Platt (1978, 1982), Mitchell et al. (1993), and Shaw (1997) identified three superimposed intrusive centers for the Coldwell Alkaline Complex. From east to west, they are Center I, Center II, and Center III. Paleomagnetic work conducted by

Ashley et al. (2012) suggested that Centers I & III have identical ages, and that both are older than Center II. Center I includes the Eastern Gabbro, the Western Gabbro, amphibole quartz syenite, iron-rich augite syenite, and mafic volcanic and subvolcanic rocks (Walker et al., 1993). Center II consists of undersaturated alkaline rocks including alkaline gabbros and syenites (Mitchell and Platt, 1978, 1982; Laderoute, 1988). Center III is composed mainly of syenites and quartz syenites which intruded into most other phases of the complex and exhibit various degrees of crustal contamination (McLaughlin and Mitchell, 1989).

According to previous studies of Shaw (1994, 1997) the Eastern gabbro (Fig. 5-1) formed by multiple intrusions of subalkaline basaltic magma into a partial ring dike structure that cut the Archean country rock. Good et al. (2015) identified nine major lithologies that were further grouped into three major distinctive magmatic series based on new mapping of stripped areas and core logging. From oldest to youngest, they are the meta-basalt, the Layered Series, and the Marathon Series. The meta-basalt has undergone pyroxene hornfels grade metamorphism as a result of the heat from later magma intrusions (Good et al., 2015). The Layered Series constitutes the main part of the Eastern gabbro and is composed of massive to modally layered olivine gabbro with a lesser amount weakly layered oxide augite melatroctolite. Contacts between these units are typically gradational. In addition, the gabbroic anorthosite is believed to be part of the Layered Series based on geochemical evidence provided by Good et al. (2015). However, it is presumably an older Layered Series phase based on outcrop where gabbroic anorthosite xenoliths and blebs are wrapped by olivine gabbro and oxide augite melatroctolite layers (Good et al., 2015). The Marathon Series is younger and consists of the Two Duck Lake gabbro, small intrusions of apatitic clinopyroxenite and oxide melatroctolite, and a thin continuous layered sill composed of augite troctolite and wehrlite.

5.3 Sampling and analytical equipment

Powders and rock specimens were obtained from 5 diamond drill holes at Area 41 (SL-13-34, SL-13-36, and SL-13-41), Four Dams (FD-13-34), and WD zone (MW-07-06). Locations of these three areas are shown in Figure 5-1. All these drill holes intersect a significant portion of the Layered Series, their drilling parameters are tabulated in Table 5-1.

Table 5-1. Drilling parameters of selected drill holes.

Area	DDH	Azimuth/°	Collar/°	Total Depth/m	Interval of the Layered Series/m
Area 41	SL-13-34	19.56	-80	201	2.36-62.50
	SL-13-36	22.07	-44.59	228	9.4-34.25
	SL-13-41	18.36	-80.05	291	1.65-131.19
Four Dams	FD-13-34	32.9	-69.6	375	4.9-226.3
WD zone	MW-07-06	89	-60	168	3.4-49.39

Powdered samples of different layered series samples were collected down drill holes using a Thermo scientific portable grinder. The detailed sampling protocols have been described in Chapter 2. All powders were initially analyzed by using a portable X-ray fluorescence, in order to select a subset of representative powdered samples (n=87) for laboratory-based whole-rock analyses. Locations of the selected powdered samples are given in Figure 5-2. After further pulverization, the powders were sent to ALS Mineral Divisions in Vancouver and Thunder Bay for lithogeochemical analyses. Both labs analyzed major elements by inductively coupled plasma (ICP)-atomic emission spectroscopy (AES) on a minimum 2 g of pulp samples after lithium borate fusion. Trace elements were analyzed by ICP-mass spectroscopy (MS) on 2 g of sample after lithium borate fusion. Total S was determined using a Leco combustion furnace on a 0.01 to 0.1g of sample, which is heated to roughly 1350°C in an induction furnace. SO₂ is produced through a reaction with oxygen and is measured by an infra-red detector. Ferrous iron was determined by H₂SO₄-HF acid digestion and titration on 1 g of sample. Quality-

control was conducted based on ALS Chemex quality-control procedures which involve analyses on a wide array of standards, blanks, and duplicates after each batch of samples. The analytical error with 95% confidence (2σ) is estimated through replicate measurements on duplicates prepared for our routine laboratory-based analyses. Laboratory-based whole-rock analyses for different units of different localities are summarized in Table 5-2.

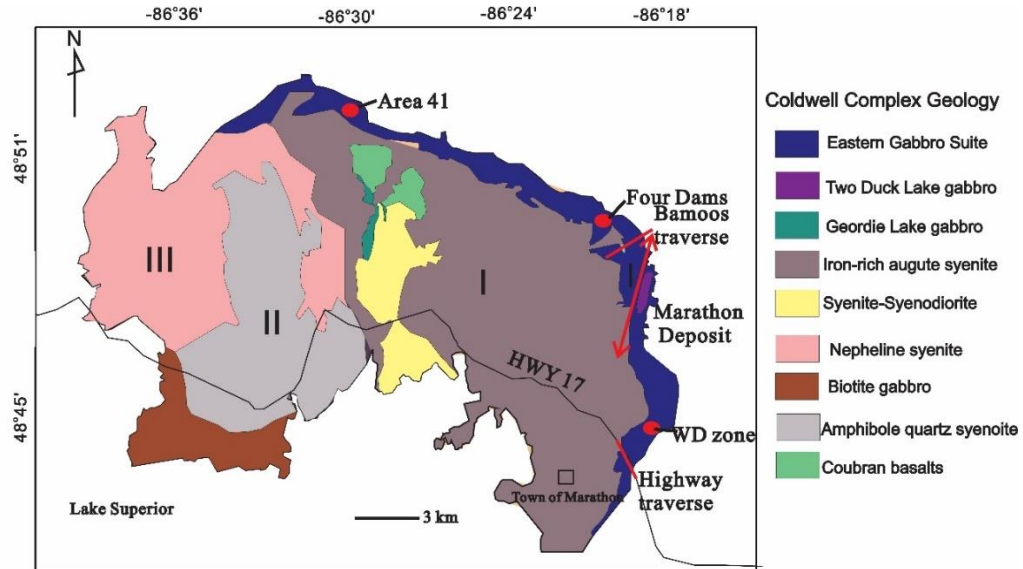

Figure 5-1. Geological map of the Coldwell Alkaline Complex, situated on the northern shore of Lake Superior. The intrusive centers have been shown by Roman numerals (modified after Mulja and Mitchell, 1991). Locations of Area 41, Four Dams, and WD zone are represented as three red dots, Bamoos and Highway traverses studied by Shaw (1997) are represented as two red lines, the Marathon deposit is indicated using a double-arrow line (Simplified after Walker et al., 1993 and Good et al., 2015).

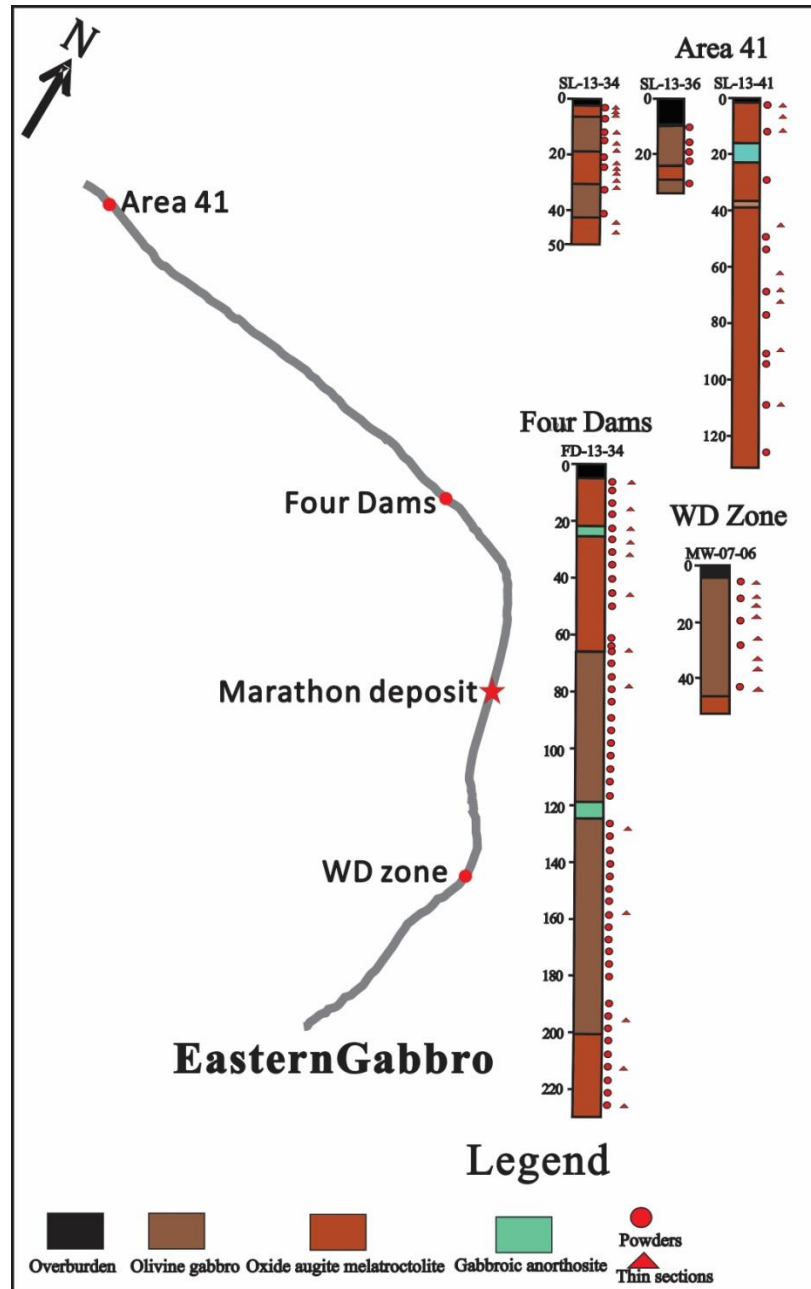

Figure 5-2. Sampling locations for powders (circles) and rock specimens (triangles) from 5 diamond drill holes: MW-07-06 at WD zone, FD-13-34 at Four Dams, and SL-13-34, SL-13-36 and SL-13-41 at Area 41. The columns represent the geological log of each of the drill holes. The outer contact of the Eastern Gabbro is represented by the thick grey line and study areas are represented by red dots. The location of the Marathon Cu-Pd deposit is indicated by a red star.

Table 5-2. Average major and trace element compositions. Number in parentheses represents number of samples analyzed for each unit; SD=1 σ standard derivation for sample set.

Polished thin sections representative of each gabbro unit in the Layered Series were prepared from selected drill holes at an interval between 5 and 20 meters (n=36, Fig. 5-2). All polished thin sections were then carbon-coated and analyzed by a JEOL JXA-8530F field emission electron microprobe analyses at Western University. Major and minor constituents of olivine, clinopyroxene, plagioclase, alkali feldspar, and biotite were analyzed using an accelerating voltage of 15 keV and a beam current of 20 nA. The beam was focused to a 1 μm spot for analyzing olivine and clinopyroxene, and to a 5 μm spot for analyzing plagioclase, alkali feldspar, and biotite. The peak counting time was 30 s for all elements and background counts were a total of 30 s. A variety of synthetic and natural standards (Table 4-4 in Chapter 4) were used to calibrate different elements during probe analyses. The analytical precision for probe analyses has been determined in Chapter 3. Results are summarized in Table 5-3.

Table 5-3. Mg# of olivine, Mg# of clinopyroxene, and anorthite content of plagioclase data determined by probe for the Layered Series samples of different areas. SD values refer to 1 σ standard deviations of measurements on 3 to 5 grains. N/A means the analysis is not available.

5.4 Petrography

5.4.1 *Olivine gabbro*

The olivine gabbro has an intergranular texture along the entire length of the Eastern Gabbro examined. It is medium grained (1-4 mm) and shows massive to rhythmic layering defined by gradational changes in the abundance of plagioclase, or alternations of clinopyroxene-rich and plagioclase-rich sublayers (Fig. 5-3A). Major mineral abundances were estimated using the combination of petrography and image analysis of thin sections (Photoshop), which vary subtly at different areas, and are composed of, in decreasing order of abundance, euhedral plagioclase (40-60 modal%), subhedral clinopyroxene (15-30 modal%), subhedral olivine (10-15 modal%). Plagioclase has bimodal size distribution. Generally, plagioclase is medium-grained and subhedral, but locally finer grained anhedral plagioclase occurs within olivine and clinopyroxene (Figs. 5-4A and B). Olivine locally is rimmed by clinopyroxene (Fig. 5-4C), indicating its crystallization sequence is, from early to late, plagioclase, olivine, and clinopyroxene. Minor mineral phases in the olivine gabbro include less than 10 modal percent fine-grained apatite and magnetite, and less than 5 modal percent anhedral biotite. The apatite and magnetite typically are enclosed in, or less commonly interstitial to, olivine and plagioclase, and the biotite occurs either as an interstitial phase, or as a poikilitic phase enclosing plagioclase, olivine, and clinopyroxene (Fig. 5-4D). Plagioclase in the olivine gabbro shows weak to moderate sericite and albite alteration, and olivine and clinopyroxene have undergone weak alteration to chlorite or actinolite.

Less than 8 modal percent medium-grained subhedral alkali feldspar observed in the Layered Series gabbro from Area 41 and WD zone. By contrast, negligible alkali feldspar was observed in the Layered Series gabbro from Four Dams. The alkali feldspar is perthite which partially overprints and encloses euhedral or wormy-like plagioclase that formed the myrmekite texture (Figs. 5-4E, 5-5A and B).

5.4.2 Oxide augite melatroctolite

The oxide augite melatroctolite unit has a different mode of occurrence at Four Dams and Area 41. At Four Dams, this unit occurs at the top and bottom of the Layered Series, with the olivine gabbro in between, whereas at Area 41 oxide augite melatroctolite is interlayered with the olivine gabbro or locally is present as a separate massive layer. A small amount of oxide augite melatroctolite is observed in the Layered Series at WD zone.

The oxide augite melatroctolite is medium-grained and has textures similar to those of the olivine gabbro. It displays weak modal layering and is distinguished from other units by a great abundance (10 to 20 modal %) of disseminated magnetite. Mineral abundances of this unit are similar at different areas, which typically consist of, in decreasing order of abundance, olivine (20-45 modal%), plagioclase (15-30 modal%), clinopyroxene (10-20 modal%), magnetite, and apatite (<10 modal%). However, the oxide augite melatroctolite from Area 41 and WD zone also contains up to 8 modal percent alkali feldspar (perthite) whereas negligible alkali feldspar is observed in the oxide augite melatroctolite from Four Dams. Locally, the plagioclase presents deformed twinning (Fig. 5-4F), indicating the post-cumulus compaction during formation of this unit. At Four Dams, the upper oxide augite melatroctolite contains slightly higher abundances of olivine and magnetite than the lower oxide augite melatroctolite. Olivine and clinopyroxene are euhedral-subhedral, and occur interstitial to subhedral to anhedral plagioclase clusters. Magnetite and apatite are generally enclosed by, or are less commonly interstitial to olivine and plagioclase. The oxide augite melatroctolite contains disseminated sulfide minerals (2-3 modal %) that are dominantly fine-grained pyrrhotite with trace chalcopyrite.

5.4.3 Gabbroic anorthosite

Gabbroic anorthosite typically occurs throughout the Layered Series as meter-sized xenoliths (Fig. 5-3B), or as large units having strike lengths of several hundred

meters. It has a very distinctive mottled appearance and consists of approximately 75-90 modal percent medium grained, subhedral to anhedral plagioclase, very coarse grained (>4 mm) clinopyroxene (3 modal %) and olivine (2 modal %) oikocrysts, and 5 modal% medium to coarse grained, interstitial to poikilitic magnetite.

Figure 5-3. Field pictures of the Layered Series gabbro. (A) Outcrop showing the rhythmic layering of the olivine gabbro at Four Dams area, note the alternation of plagioclase-rich and clinopyroxene-rich sublayers; (B) Outcrop showing the rounded blocks of gabbroic anorthosite within the Layered Series, layering wraps around the xenoliths.

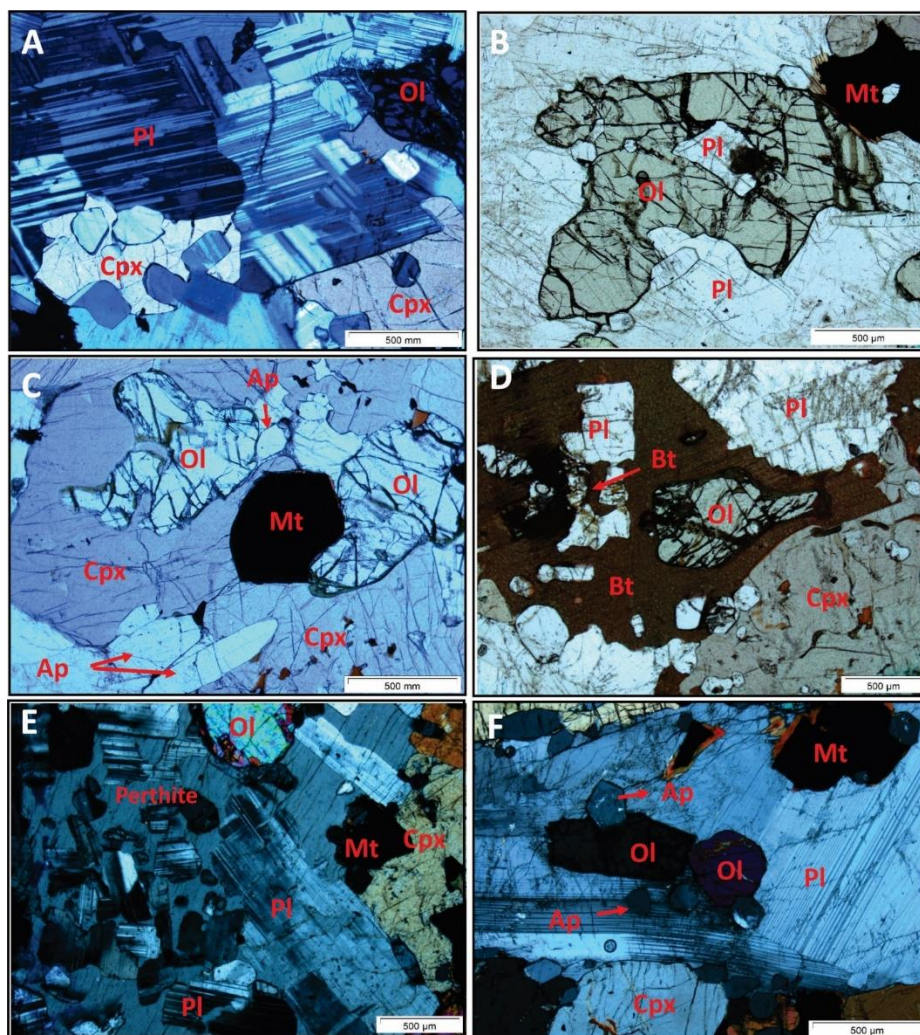

Figure 5-4. Photomicrographs showing textures and mineral compositions of different units. (A) FD-13-34-64.6 olivine gabbro, cross-polar transmitted light photomicrograph showing the Cpx partially encloses and bisects Pl chadocrysts; (B) SL-13-41-63.2 olivine gabbro, plane polarized light photomicrograph showing Ol encloses Pl chadocrysts, and Cpx is interstitial to Pl; (C) FD-13-34-46.1 olivine gabbro, plane polarized light photomicrograph showing Ol is rimmed by Cpx; (D) SL-13-34-32 olivine gabbro, plane polarized light photomicrograph showing Ol and Pl are surrounded by Bt, note the locally resorption of Pl by Bt; (E) SL-13-34-5.1 olivine gabbro, cross-polar transmitted light photomicrograph showing perthite oikocrysts encloses many euhedral platy Pl grains; (F) FD-13-34-226.3 oxide augite melatroctolite, cross-polar transmitted light photomicrograph showing the deformed twinning of plagioclase. Abbreviations Ol: olivine, Cpx: clinopyroxene, Pl: plagioclase, Mt: Magnetite, Ap: apatite, Bt: biotite.

(A) SL-13-41-3 oxide augite melatroctolite, the wormy shaped Pl grains within the perthite; (B) SL-13-34-13.3 olivine gabbro, the Ab exsolution in orthoclase host forming the typical perthite in the Layered Series rocks from Area 41. Abbreviations Ab: albite, Or: orthoclase, Pl: plagioclase, Mt: Magnetite, Ilm: ilmenite.

5.5 Down-hole profiles

5.5.1 Four Dams

Down-hole variations in Mg#s of olivine and clinopyroxene, anorthite content of plagioclase, whole-rock SiO_2 , Fe_2O_3 , P_2O_5 , La, La/Sm, Al_2O_3 , CaO, K_2O , Rb, Sr, Ba, Zr, and Gd/Yb for Layered Series units of drill hole FD-13-34 are displayed in Figure 5-6 and summarized in Table 5-3. Generally, from the upper oxide augite melatroctolite, through the olivine gabbro, to the lower oxide augite melatroctolite, three different trends are observed. The upper oxide augite melatroctolite unit has relatively constant mineral chemical compositions and whole-rock P_2O_5 , La, and Zr concentrations. Concentrations of the remaining whole-rock major and trace elements in the upper oxide augite melatroctolite are highly variable and are generally lower than those in the underlying olivine gabbro except Fe_2O_3 .

Throughout the thick unit of olivine gabbro, olivine, clinopyroxene and plagioclase trend towards more evolved compositions down-hole whereas whole-rock incompatible elements such as La and Zr generally increase with depth. In addition, P_2O_5 contents throughout the entire olivine gabbro are almost constant (1.5-2 wt.%). However, in detail there are step like variations in abundances of Rb, Sr, Ba and Zr that approximately correspond to variations in La/Sm and Gd/Yb that taken together

indicate the olivine gabbro can be subdivided into four sub units (I-IV). Table 5-4 summarizes mineral compositions and whole-rock La, Rb, Sr, Ba, Zr, La/Sm, and Gd/Yb for all the subdivided units identified at FD-13-34. These variations suggest that at least four pulses of magma were involved in generation of the current package of olivine gabbro rocks. In the lower oxide augite melatroctolite, the down-hole variations of major and trace elements are more consistent compared to the upper oxide augite melatroctolite unit. For instance, whole-rock Fe_2O_3 , P_2O_5 , and La increase with depth whereas the rest of whole-rock variables generally decrease with depth till to the base of the Layered Series. However, there are an inadequate number of rock samples from the lower oxide augite melatroctolite unit to fully interpret the mineral chemistry of this unit.

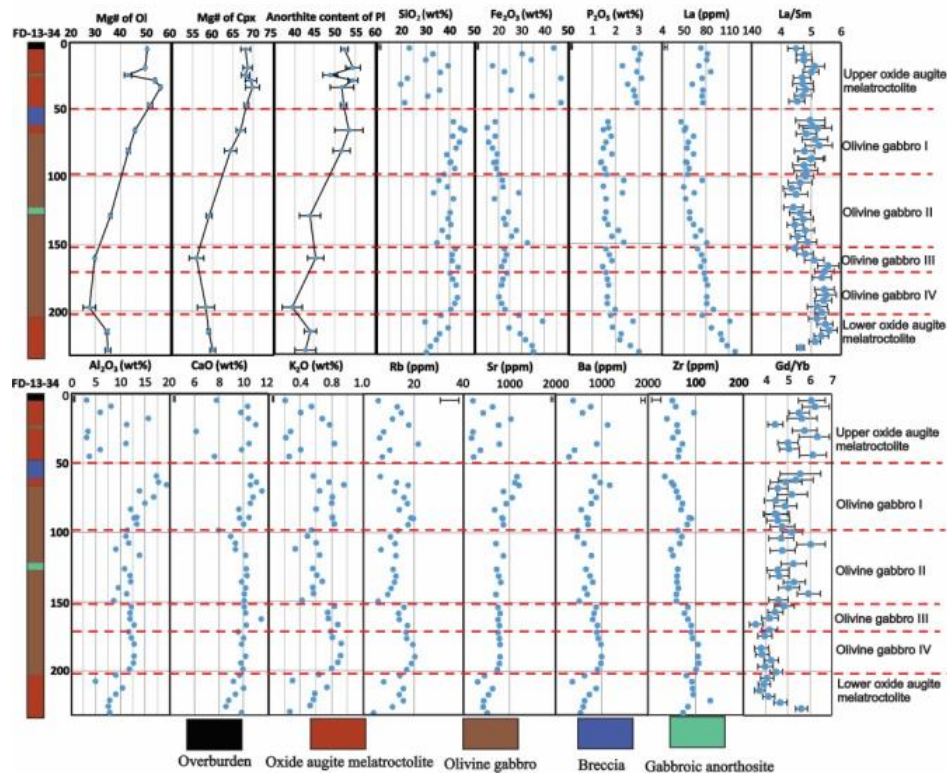

Figure 5-6. Down-hole mineral chemical and lithogeochemical profiles throughout the Layered Series gabbro units for drill hole FD-13-34 of Four Dams area. Note the coupled reverse differentiation trends for Mg#s of Ol and Cpx, anorthite content of Pl, and whole-rock La and Zr. The error bar for whole-rock analysis represents 2σ analytical precision determined by multiple analyses on the same sample. The error bar for mineral chemical analysis represents 1σ sample error determined by analyses on 3-4 spots of 3-5 grains of each type of mineral for each sample. Abbreviations: Ol-Olivine; Cpx-Clinopyroxene; Pl-Plagioclase.

Table 5-4. Summary of Mg#s of olivine and clinopyroxene, anorthite content of plagioclase, and whole-rock Rb, Sr, Ba, Zr, La/Sm, and Gd/Yb for sub-units identified in drill hole FD-13-34. Abbreviations: Ol-olivine, Cpx-clinopyroxene, Pl-plagioclase, OAM-oxide augite melatroctolite, OG- olivine gabbro.

Unit	Mg# of Ol	Mg# of Cpx	An content of Pl	Rb	Sr	Ba	Zr	La/Sm	Gd/Yb
Upper OAM	50-60	65-70	50-55	5-18	200-800	200-1000	40-80	4.5-5	5.0-6.4
OG I	40-50	62-68	50-53	12-20	700-1200	500-1000	50-90	4.8-5.3	4.5-5.6
OG II	30-40	56-62	45-50	6-13	550-800	450-800	60-70	4.3-4.8	4.6-6.0
OG III	30-32	55-57	~45	14-18	760-800	820-930	80-90	4.5-5.3	4.2-4.8
OG IV	~29	~58	~40	17-21	750-820	910-1000	90-105	5.4-5.6	3.6-4.3
Lower OAM	30-35	58-60	43-45	8-16	320-650	400-900	80-100	5.2-5.6	3.8-5.6

5.5.2 Area 41

Mineral chemical and whole-rock lithogeochemical profiles through the Layered Series in drill hole SL-13-34 at Area 41 are displayed in Figure 5-7. Near the top of the drill hole Mg#s of olivine and clinopyroxene, and anorthite content of plagioclase decrease slightly to around 10m, and then they increase with depth to the base of the Layered Series. It is notable that the consistent down-hole mineral chemical variations are not affected by the changes in rock types, *e.g.*, from the olivine gabbro to oxide augite melatroctolite. Combining this observation with the similarity of the REE distribution patterns for the olivine gabbro and oxide augite melatroctolite from Area 41, as will be shown later, it is reasonable to suggest that olivine gabbro and oxide augite melatroctolite are the same unit and that differences in mineral abundances (particularly magnetite) are a result of mechanical mineral sorting process.

Profiles of trace elements La, Zr, Gd, and Yb, and ratios of La/Sm and Gd/Yb fluctuate down hole, suggesting that multiple pulses of related intrusions formed the package of the Layered Series rocks. Generally, the down-hole variations of La and Zr are similar to mineral chemical profiles, which are in the opposite sense to the down-hole variation of Ba concentrations. The down-hole variation in whole-rock P₂O₅ is similar to La throughout the total package of the Layered Series, indicating

that La is mainly controlled by apatite. In addition, K₂O, Ba, Sr, and Rb have broadly similar down-hole profiles throughout the Layered Series.

The inspection of mineral compositions and whole-rock Zr, La/Sm, and Gd/Yb for olivine gabbro between 7 and 18 m down bore hole SL-13-34 closely resembles the olivine gabbro sub-unit III in bore hole FD-13-34, whereas the olivine gabbro from 21 to 45 m down bore hole SL-13-34 resembles the olivine gabbro sub-unit I in FD-13-34, respectively (see Table 5-4 for reference). However, it is noteworthy that the olivine gabbro at 7-18 and 21-45 m down the bore hole SL-13-34 also contains higher Ba, Sr, and Rb contents than the olivine gabbro sub-units III and I at FD-13-34, respectively.

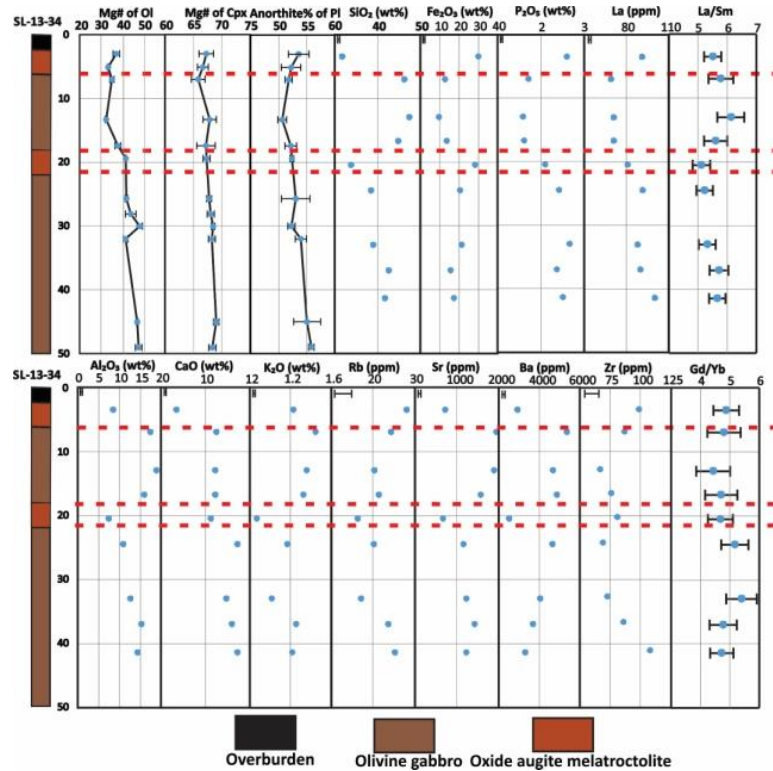

Figure 5-7. Down-hole mineral chemical and lithogeochemical profiles throughout the Layered Series units for drill hole SL-13-34 at Area 41. Note the similar trends between Mg#s of Ol and Cpx, anorthite content of Pl, and whole-rock La and Zr. The error bar for whole-rock analysis represents 2 σ analytical precision determined by multiple analyses on the same sample. The error bar for mineral chemical analysis represents 1 σ sample error determined by analyses on 3-4 spots of 3-5 grains of each type of mineral for each sample. Red dashed lines show the contact between olivine gabbro and oxide augite melatroctolite. Abbreviations: Ol-Olivine; Cpx-Clinopyroxene; Pl-Plagioclase.

5.5.3 WD zone

Down-hole profiles of mineral chemical and whole-rock compositions for drill hole MW-07-06 at WD zone are displayed in Figure 5-8. Down-hole variations in Mg#s of olivine and clinopyroxene, and anorthite content of plagioclase present an overall increasing trend with depth. La and Zr also present a general increasing trend with depth, in contrast to Ba which decreases with depth to the base of the sampled interval. These trends are similar to what is observed at Area 41 (SL-13-34). The trends for mineral compositions, Zr, La/Sm, and Gd/Yb resembles olivine gabbro subunit IV at Four Dams (FD-13-34), but, similar to Area 41, contain higher Rb, Sr, and Ba.

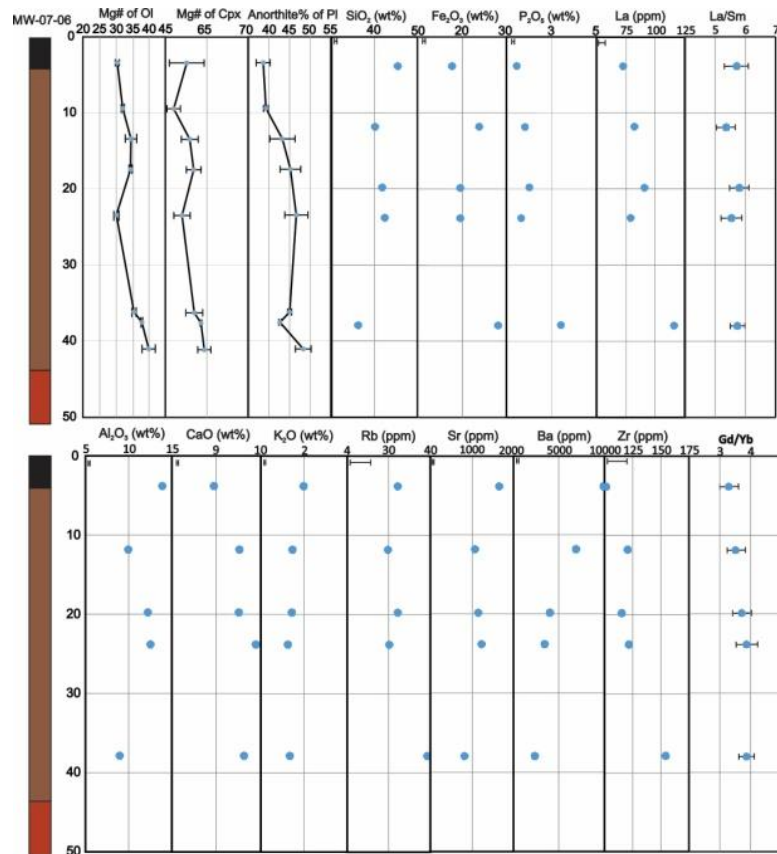

Figure 5-8. Down-hole mineral chemical and lithogeochemical profiles throughout the Layered Series gabbro units for drill hole MW-07-06 of WD zone area. The error bar for whole-rock analysis represents 2 σ analytical precision determined by multiple analyses on the same sample. The error bar for mineral chemical analysis represents 1 σ sample error determined by analyses on 3-4 spots of 3-5 grains of each type of mineral for each sample. Abbreviations: Ol-Olivine; Cpx-Clinopyroxene; Pl-Plagioclase, symbols as in Figure 5-7.

5.6 Mineral compositions

Mineral chemical compositions for the units at Area 41 and Four Dams are examined in this section. Note that due to the small amount of the gabbroic anorthosite in the Layered Series as well as the unavailable rock specimens for this unit, the gabbroic anorthosite is ignored in the following examination.

5.6.1 Summary of mineral chemical results

5.6.1.1 Olivine, clinopyroxene and plagioclase

Mg#s of olivine and clinopyroxene and anorthite content of plagioclase for olivine gabbro and oxide augite melatroctolite of the Layered Series are summarized in Figure 5-9. Note that olivine and clinopyroxene in our samples do not show obvious zoning, but plagioclase is normally zoned because of the relatively slow Na/Ca exchange at the crystal scale (Grove et al., 1984), compositional data from plagioclase cores are adopted here to represent mineral chemical compositions in each sample. Figure 5-9 shows that the olivine gabbro and oxide augite melatroctolite at Area 41 have similar values in Mg#s of olivine and clinopyroxene, and anorthite content of plagioclase, but overall the oxide augite melatroctolite seems to be more primitive than the olivine gabbro. At Four Dams, the oxide augite melatroctolite appears to be more primitive than its olivine gabbro counterpart. Generally, the Layered Series rocks at Area 41 are slightly more primitive than those at Four Dams area. It is also noteworthy that the Layered Series units at Four Dams have relatively wide ranges in both Mg#s of olivine and clinopyroxene. This is in contrast to the Layered Series units at Area 41 where values of Mg# of olivine are significantly more variable than those of Mg# of clinopyroxene.

Figure 5-9. Box and whisker plots summarizing Mg# of olivine, Mg# of clinopyroxene, and anorthite content of plagioclase for the Layered units of different areas.

5.6.1.2 Biotite, orthoclase and plagioclase

Barium, Sr and K₂O contents of biotite, alkali feldspar (dominantly orthoclase), and plagioclase in the Layered Series units at Area 41 and Four Dams are tabulated in Table 5-5. Biotite and plagioclase in Area 41 units contain higher Ba and Sr contents, respectively, than at Four Dams, and alkali feldspar in Area 41 units contain significantly higher Ba (>60000 ppm) than both biotite and plagioclase. Note that mineral descriptions for olivine gabbro and oxide augite melatroctolite at each area are grouped together to facilitate the description. Figure 5-10 shows that there is a positive correlation between anorthite content and Ba concentrations in plagioclase for units at Area 41. By contrast, the units at Four Dams display an overall negative correlation between these two variables.

Table 5-5. Ba, Sr and K₂O concentrations in alkali feldspar, biotite and plagioclase of the Layered Series samples from different localities, results were determined electron microprobe analyses. SD refers to 1 σ sample variability determined by multiple analyses on 3-5 grains of each mineral type in each sample. N/A means thin sections are not available.

Mineral	Element		Area 41	Four Dams
Alkali feldspar	Ba (ppm)	Avg	66000	N/A
		SD	10000	N/A
	Sr (ppm)	Avg	3400	N/A
		SD	620	N/A
	K ₂ O (wt %)	Avg	7.9	N/A
		SD	1.33	N/A
Biotite	Ba (ppm)	Avg	13900	5900
		SD	6940	975
	Sr (ppm)	Avg	240	300
		SD	120	150
	K ₂ O (wt %)	Avg	8.7	8.8
		SD	0.40	0.15
Plagioclase	Ba (ppm)	Avg	3000	1600
		SD	730	540
	Sr (ppm)	Avg	2800	2100
		SD	390	270
	K ₂ O (wt %)	Avg	0.8	0.8
		SD	0.11	0.11

Figure 5-10. Relationships between anorthite content of plagioclase and Ba concentrations in plagioclase for the Layered Series units from Area 41 and Four Dams. Note that units at Four Dams and Area 41 has two different trends. R^2 refers to the coefficient of determination between anorthite content of plagioclase and Ba in plagioclase. The error bar represents 1 σ sample variability determined through multiple analyses on at least 3 plagioclase grains in each sample.

5.6.2 Fe/Mg exchange between olivine and clinopyroxene

Down-hole variations in Fe/Mg exchange partition coefficient ($Kd_{Fe/Mg}^{Ol/Cpx} = (Fe/Mg)_{Ol}/(Fe/Mg)_{Cpx}$, in mole) for the Layered Series intersected by SL-13-34 and FD-13-34 are summarized in Table 5-6 and shown in Figure 5-11. The red dashed lines in this diagram indicate the equilibrium $Kd_{Fe/Mg}^{Ol/Cpx}$ at 1100 °C (1.8) based on Loucks (1996b). Note that 1100 °C represents the forming temperature of the Layered Series units according to clinopyroxene-orthopyroxene geothermometer results from Shahabifar (pers. comm. 2016). Figure 5-11 shows that there is a general down-hole decrease in $Kd_{Fe/Mg}^{Ol/Cpx}$ for the Layered Series at Area 41, with values becoming increasingly closer to 1.8 with depth. By contrast, the Layered

Series at Four Dams presents a down-hole increasing trend in $Kd_{Fe/Mg}^{Ol/Cpx}$, with values becoming increasingly deflected away from 1.8 with depth.

Table 5-6. The summary of $Kd_{Fe/Mg}^{Ol/Cpx}$ for the Layered Series units intersected by drill hole SL-13-34 and FD-13-34.

Drill hole	Depth/m	Unit	(Fe/Mg) _{cpx}	(Fe/Mg) _{Ol}	$Kd_{Fe/Mg}^{Ol/Cpx}$
SL-13-34	3.0	Oxide augite melatroctolite	0.49	1.69	3.47
	5.1	Oxide augite melatroctolite	0.50	1.99	3.99
	7.0	Olivine gabbro	0.52	1.84	3.55
	13.3	Olivine gabbro	0.47	2.08	4.39
	17.4	Olivine gabbro	0.49	1.63	3.35
	19.4	Oxide augite melatroctolite	0.49	1.40	2.88
	25.7	Oxide augite melatroctolite	0.48	1.38	2.91
	28.1	Oxide augite melatroctolite	0.47	1.27	2.71
	30.0	Oxide augite melatroctolite	0.46	1.07	2.33
	32.0	Olivine gabbro	0.46	1.40	3.02
	45.0	Olivine gabbro	0.45	1.12	2.51
	49.0	Oxide augite melatroctolite	0.46	1.10	2.36
FD-13-34	5.0	Oxide augite melatroctolite	0.47	0.98	2.08
	18.6	Oxide augite melatroctolite	0.46	1.01	2.20
	24.0	Olivine gabbro	0.47	1.33	2.83
	27.9	Oxide augite melatroctolite	0.44	0.86	1.96
	33.0	Oxide augite melatroctolite	0.43	0.79	1.82
	46.1	Oxide augite melatroctolite	0.46	0.93	2.00
	64.6	Oxide augite melatroctolite	0.49	1.18	2.39
	79.6	Olivine gabbro	0.55	1.31	2.38
	127.3	Olivine gabbro	0.69	1.77	2.56
	158.6	Olivine gabbro	0.79	2.34	2.98
	194.8	Olivine gabbro	0.72	2.60	3.63

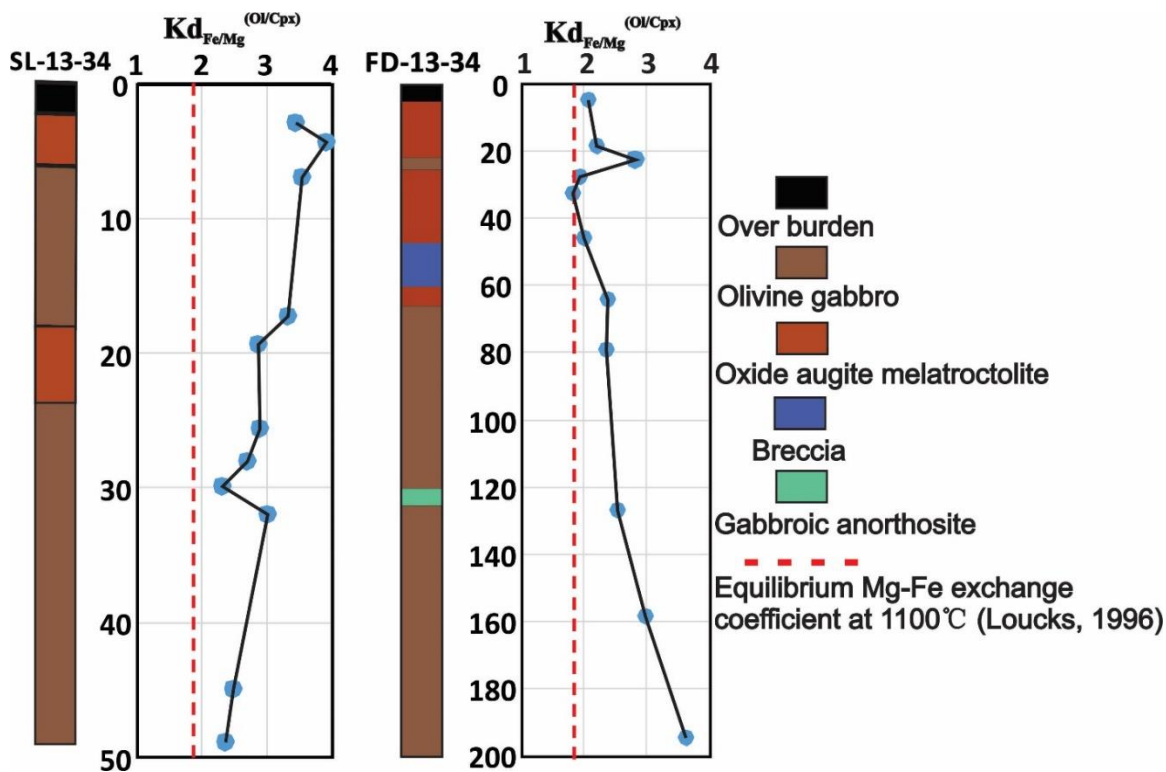

Figure 5-11. Down-hole variations in Mg-Fe exchange coefficient (K_d) between olivine and clinopyroxene for the Layered Series units intersected by SL-13-34 at Area 41 and FD-13-34 at Four Dams. Note the different down-hole trends for units at Four Dams and Area 41. The equilibrium coefficient (1.80) at 1100 °C based on Loucks (1996) is indicated using a red dashed line.

5.7 Geochemical characteristics

Shaw (1997) investigated down-hole mineral chemical profiles of the Layered Series at Bamooos and Highway traverses (locations are indicated in Figure 5-1), and found that the down-hole trends were not consistent and could not be correlated. In this study the Layered Series at Area 41 and WD zone exhibits different down-hole profiles compared to those at Four Dams, in agreement with Shaw (1997). The major differences between the two groups are the higher abundances of Ba, Sr, and Rb at Area 41 and WD zone. These differences are consistent with the mineral chemical observations described above and suggest that different processes must have taken place for development of the Layered Series at these locations. To further investigate igneous processes active in the Layered Series we examined additional geochemical features at Area 41 and Four Dams.

5.7.1 General element ratio diagram

A first step in comparing the Layered Series gabbro units at different areas is to verify the classification scheme that was used in the field and subsequent petrography. Good et al. (2015) found Pearce-General Element diagram of $(\text{Ca}/\text{Si}-5/3\text{P})$ (in mole) vs. Mg/Si (in mole) (Fig. 5-12) was useful in illustrating variations in olivine, clinopyroxene, and plagioclase in all rock types. Furthermore, this diagram can neglect the potential influence of sulfides, magnetite, apatite, and biotite because of normalizing molar proportions to Si and subtracting the proportion of Ca contributed by apatite, thus it is very useful in comparing different rock units. Note that plagioclase with different anorthite content are plotted along the vertical axis. In addition, Figure 5-12 includes average mineral chemical compositions of olivine, clinopyroxene, and plagioclase for the Layered Series gabbro from Area 41 and Four Dams as determined by electron microprobe analyses. This diagram successfully separates different layered series rocks. For example, the olivine gabbro at Area 41 and Four Dams plot close to the plagioclase with a composition of An_{50} , similar to average compositions of the plagioclase determined by electron microprobe analyses. Oxide augite melatroctolite samples display a nearly horizontal trend that is closer to the right hand side of the diagram and intersects clinopyroxene-olivine tie lines approximately at the midpoint, indicating this unit contains a variable amount of plagioclase and almost equal proportions of clinopyroxene and olivine. These observations are in good agreement with the petrography.

Figure 5-12. General element ratio diagram for major rock units of the Layered Series. Molar proportions of whole-rock data are plotted relative to major minerals. Grey dashed lines are clinopyroxene-olivine and clinopyroxene-plagioclase tie lines for the Layered Series gabbro at Area 41 and Four Dams. Average Mg# of olivine, Mg# of clinopyroxene, and anorthite content of plagioclase for the Layered Series gabbro at Area 41 and Four Dams are indicated using red triangles. Anorthite content of plagioclase plotted along the y-axis are values calculated based on plagioclase stoichiometry. Different sample groups are outlined with dashed circles in different colours. Average olivine and clinopyroxene compositions determined by probe analyses are indicated. Samples are corrected for Ca contained in apatite. The triangle indicates average probe analysis for the Layered Series gabbro.

5.7.2 Summary of whole-rock compositions

Concentrations of selected major and trace elements in various Layered Series units are shown in Figure 5-13. Variations in whole-rock major elements are mainly controlled by variations in major minerals. For example, the higher abundances of Fe_2O_3 , TiO_2 , P_2O_5 , MgO , and the lower abundances of SiO_2 , Al_2O_3 , K_2O , Na_2O for

the oxide augite melatroctolite compared to the olivine gabbro indicate it has more magnetite, olivine and apatite, and less plagioclase than olivine gabbro and gabbroic anorthosite. These are all consistent with petrographic observations. The olivine gabbro at Area 41 contains higher K_2O contents than other units, reflecting the presence of alkali feldspar as observed by petrography.

The olivine gabbro and oxide augite melatroctolite from Area 41 contains pronounced higher Ba contents than those from Four Dams. Zr contents in the olivine gabbro and oxide augite melatroctolite from both areas are similar.

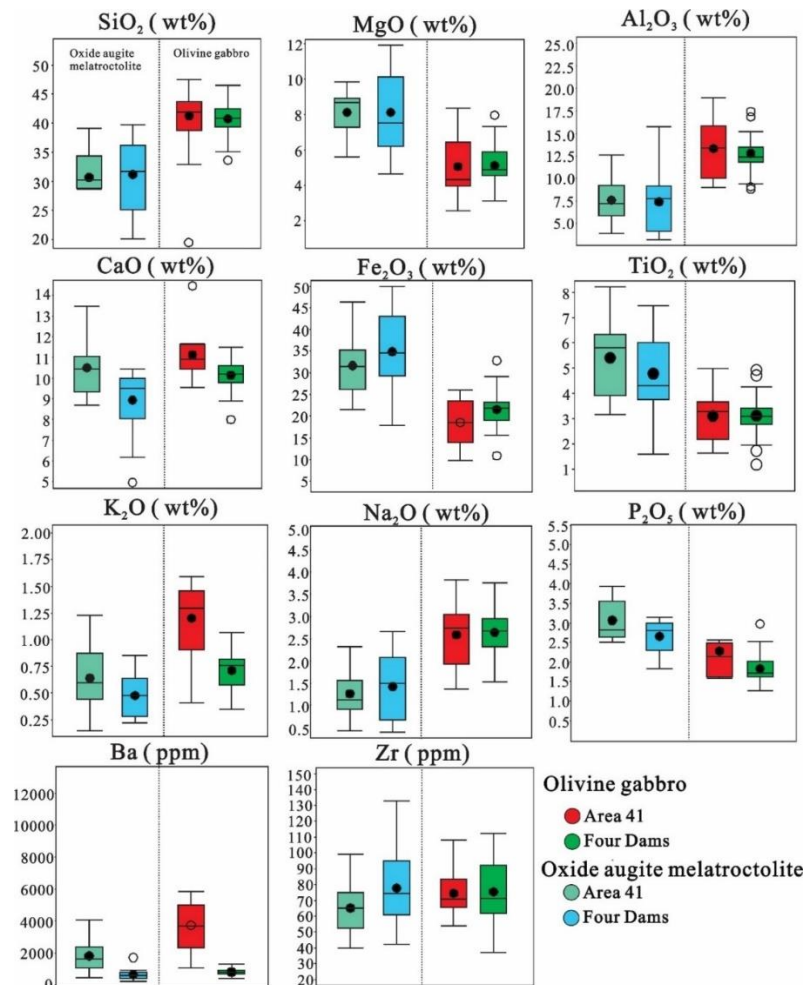

Figure 5-13. Box and whisker plots for selected major and trace elements in different rock units of different localities. Box and whisker plots are uniform in their use of the box: the bottom and top of the box are always the 25th and 75th percentile (the lower and upper quartiles, respectively), and the band near the middle of the box is always the 50th percentile (the median). The small black infilled circle is the average and the lines on the ends are the minimum and maximum values, black empty circles are outliers.

5.7.3 Distribution of trace elements

5.7.3.1 Rare Earth Element (REE)

The Primitive mantle (Sun and McDonough, 1995) normalized average abundance of rare earth elements (REE) in the olivine gabbro and oxide augite melatroctolite from Area 41 and Four Dams, are compared to the average REE abundances for the Coubran basalts from Cundari (2012) in Figure 5-14. The Coubran basalts are located in the center of the Coldwell Alkaline Complex, and Cundari (2012) considered them to be co-genetic with PGE mineralization related the Marathon Series. Three important observations on the trace element data are: 1) REE patterns for average samples of the olivine gabbro and oxide augite melatroctolite are elevated and approximately parallel to the pattern for average samples of the Coubran basalts; 2) average samples of the oxide augite melatroctolite from Area 41 and Four Dams present very similar distribution patterns with their olivine gabbro counterparts, indicating both rock types may have crystallized from similar magmas; 3) at both areas, the REE for oxide augite melatroctolite is slightly higher than for olivine gabbro; and, 4) there is a pronounced inflection point at Nd for all of the trends.

Figure 5-15A shows there is a general positive relationship between Ce and P_2O_5 for all rock types, indicating apatite is likely the controlling phase of light REE. In addition, the olivine gabbro and oxide augite melatroctolite present an increasing P_2O_5 with increasing Ce/Yb trend (Fig. 5-15B), as expected given that the LREE are more compatible in apatite than Yb (Paster, 1974).

Figure 5-14. REE contents for the Layered Gabbro at different areas, and Coubran basalt normalized to the primitive mantle values of Sun and McDonough (1995). Data of samples from Area 41 and Four Dams are prepared in the current study, data of the Coubran basalt are from Cundari (2012).

5.7.3.2 Large Ion Lithophile Element (LILE)

The observed differences in behaviour of LILE at Area 41 and Four Dams are highlighted in Figures 5-15C to F. Samples from Area 41 show a negative correlation between Ba and La, whereas samples from Four Dams present a nearly horizontal trend between Ba and La (Fig. 5-15C). All these rock units show positive Rb vs. K_2O , and Ba vs. K_2O correlations (Figs. 5-15D and E), indicating Rb and Ba are mainly controlled by potassium-bearing phases, *e.g.*, biotite, orthoclase, plagioclase, etc. However, the trends for units at Area 41 on Ba vs. K_2O and Ba vs. Sr are much steeper than for data at Four Dams (Figs. 5-15E and F).

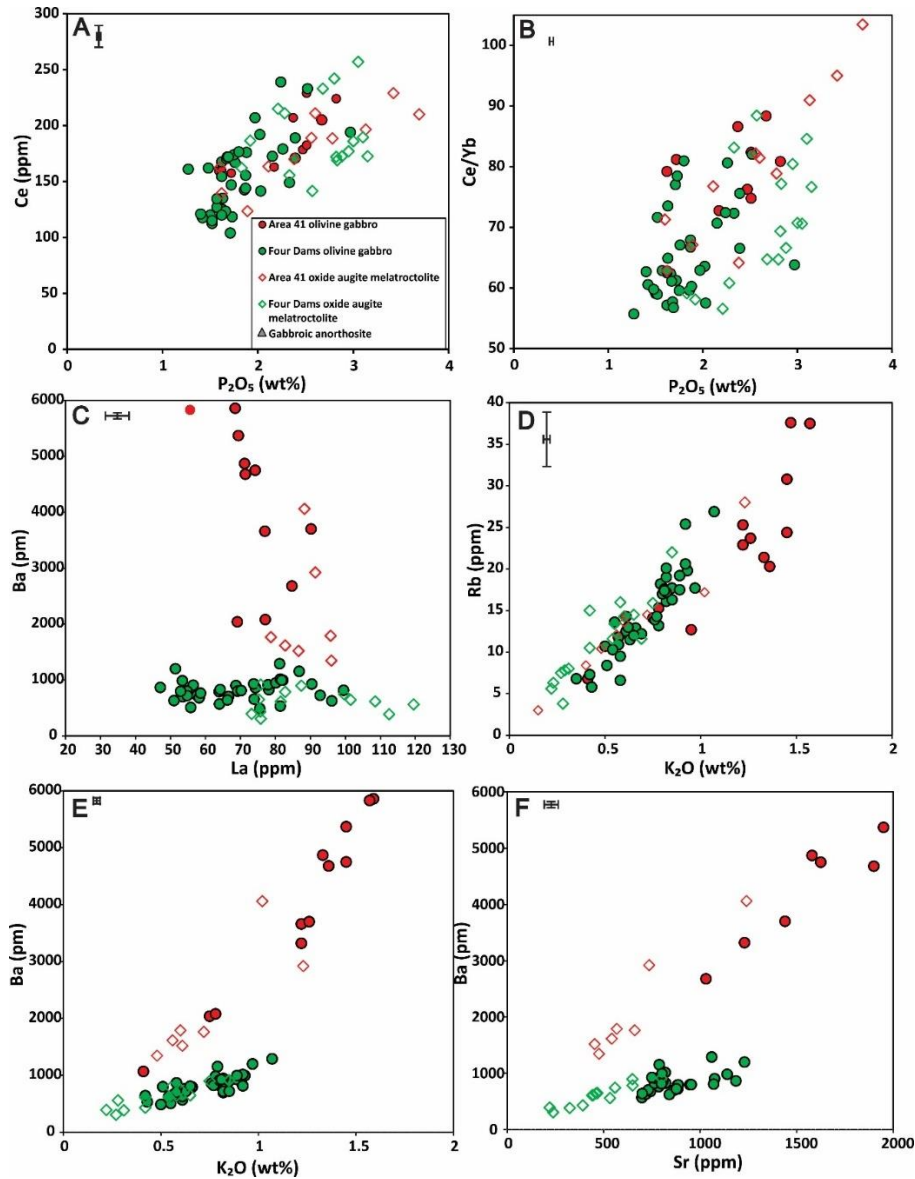

Figure 5-15. Binary diagrams correlating Ce vs. P_2O_5 , Ce/Yb vs. P_2O_5 , Ba vs. La, Rb vs. K_2O , Ba vs. K_2O , and Ba vs. Sr for various rock types. Error bar represents the 2σ analytical precision for lithogeochemical analyses, determined through repetitive analyses on duplicates.

Diagrams of Ba vs. K_2O and Ba vs. Sr (Figs. 5-15 E and F) are converted into logarithmic scale plots in Figures 5-16 and 5-17 in order to further examine the different Ba and Sr behaviours at Area 41 and Four Dams. Conducting this conversion has two purposes. First, it allows the Layered Series units at different areas to be separated into two areas without any overlaps, thus facilitating the observations. Second, in logarithmic scale plot, lines with different ratios will be parallel to each other, thus facilitating the interpretations particularly after adding

mineral control lines. Average Ba/K₂O and Ba/Sr ratios for potassium-bearing minerals such as plagioclase, orthoclase, and biotite were determined by electron microprobe analyses. This allows us to add mineral control lines on both diagrams to interpret the mineral controls of whole-rock Ba and Sr in actual rocks. Both diagrams show that whole-rock Ba and Sr concentrations are controlled by a mixture of plagioclase, biotite, and/or orthoclase. For example, whole-rock Ba and Sr concentrations in Area 41 rocks can be explained by crystallization of plagioclase, orthoclase, and biotite with volume proportions of 90:6:4, whereas those in Four Dams rocks are controlled by plagioclase and biotite with volume proportions of 90:10. These relative proportions of potassium-bearing minerals are in agreement with average mineral compositions in the actual rocks.

Figure 5-16. Logarithmic scale diagram correlating Ba with K₂O for the Layered Series units from Area 41 and Four Dams. Ba/K₂O ratios for different minerals determined by electron microprobe analyses are indicated using parallel vectors.

Figure 5-17. Logarithmic scale diagram correlating Ba versus Sr for the Layered Series units from Area 41 and Four Dams. Ba/Sr ratios for different minerals determined by electron microprobe analyses are indicated using parallel vectors. Liquid lines of descent for the Layered Series olivine gabbro from Area 41 and Four Dams are also indicated based on geochemical modeling results as will be shown in section 5.8.3. Other symbols as in Figure 5-16.

5.8 Geochemical modeling

In order to gain some insight into the parental magma of the Layered Series and evaluate whether it is co-genetic with the Coubran basalts, the Layered Series units are modeled by assuming Rayleigh fractional crystallization (RFC). Using RFC may be reasonable because the Layered Series units present consistent down-hole variations in both mineral chemical and whole-rock compositions. The equation for the RFC is:

$$C_L = C_o * F^{(D-1)}$$

where C_o is the initial concentration of the trace element, F is the fraction of melt remaining, C_L is the concentration of the trace element in the remaining melt, and D is the partition coefficient for the trace element into the mineral (Neuman et al., 1954).

The composition of instantaneous cumulate (C_c) crystallized from the residual melt is:

$$C_c = D * C_o * F^{(D-1)}$$

When more than one mineral is fractionated, D here represents the bulk partition coefficient that is calculated using the following equation:

$$D = \sum X_\Phi D^\Phi$$

where X_Φ is the weight fraction of phase Φ and D^Φ is the distribution coefficient of the trace element into phase Φ .

After constraining the starting compositions (parental magma compositions for various units), this modeling allows us to estimate concentrations of trace elements in residual liquids and instantaneous cumulates at different F . In addition, at certain F , concentrations of trace elements in generated rocks with different proportions of interstitial liquids can be calculated using the following equation:

$$C_R = C_L * (1 - \phi) + C_c * \phi$$

where C_R is the concentration of the trace element in the formed rock, ϕ is the weight proportion of cumulates in the rock.

As mentioned in section 5.5.2, the oxide augite melatroctolite is the same unit with the olivine gabbro, in order to simplify descriptions and avoid repetition, models shown here are for olivine gabbro at Four Dams and Area 41. High Field Strength Elements (HFSE) such as Nb, Zr, and La, and LILE such as Ba and Sr are selected for modelling because: 1) HFSE are often used to interpret petrogenesis of rock units because of their highly incompatible behaviour into most silicate phases; 2) Sr is a compatible element into plagioclase (the main constituent of the rock types), and Ba behaves similarly with Sr for the olivine gabbro according to the positive relationships between the two elements (Fig. 5-15F); and, 3) as mentioned above

the units at Area 41 and Four Dams have different Ba and Sr contents, modelling both elements may gain some insight on understanding these differences.

5.8.1 *The selection of partition coefficients*

The partition coefficients are critical data to establish suitable models and form the basis of all related arguments. However, the large available database of partition coefficients determined by studies over decades mean that selecting the most suitable partition coefficients is challenging. In order to constrain the usage of partition coefficients as best as possible, two strategies are applied. First, selecting partition coefficients determined in tholeiitic-alkaline basalt magma systems to minimize the effects of melt composition. Second, minimize the choice of authors because different authors may have determined the partition coefficients under different conditions including temperature, oxygen fugacity, etc. Doing this will largely reduce the biases introduced by these uncertainties. The selected partition coefficients that best satisfy the above two strategies are given in Table 5-7.

Table 5-7. Mineral/liquid partition coefficients selected in the current work. Ol-olivine, Cpx-clinopyroxene, Pl-plagioclase, Mt-magnetite, Ap-apatite, Bt-biotite.

5.8.2 HFSE

The weight proportions of the fractionated mineral phases used in modeling are 11% olivine, 28% clinopyroxene, 55% plagioclase, 2% magnetite, 4% apatite, using representative average mineral compositions of the olivine gabbro from Four Dams and Area 41. After the selection of best available partition coefficients (Table 5-7), the fitted La vs. Zr, and Th vs. Nb model curves for the olivine gabbro at Four Dams and Area 41 are displayed in Figures 5-18 A and B. Compositions of the Coubran basalts are indicated in these models for comparison. Note that Cundari (2012) subdivided the Coubran basalts into three groups (types A, B, and C), based on their incompatible element abundances and so each type is plotted for comparison.

The model curves in Figures 5-18 A and B represent a possible solution using a possible parental magma for the olivine gabbro at both areas. Note that no matter what the starting composition is, once bulk partition coefficients for modelled elements are determined, directions of these curves will not change. Possible melt starting composition that could resolve the observed rock compositions is tabulated in Table 5-8. This possibility requires a starting composition with considerably higher abundances of La, Zr, and Nb, and a lower abundance of Th than the three types of the Coubran basalts, suggesting that the Layered Series units cannot be produced directly from a Coubran basalt-like magma. Generally, La and Zr contents are similar to those in $F=0.55$ melt of the type B Coubran basalt (after fractionation of 65% olivine and 35% clinopyroxene). But Nb and Th in the possible parental magma cannot be related to the type B Coubran basalt by the mentioned fractional scheme.

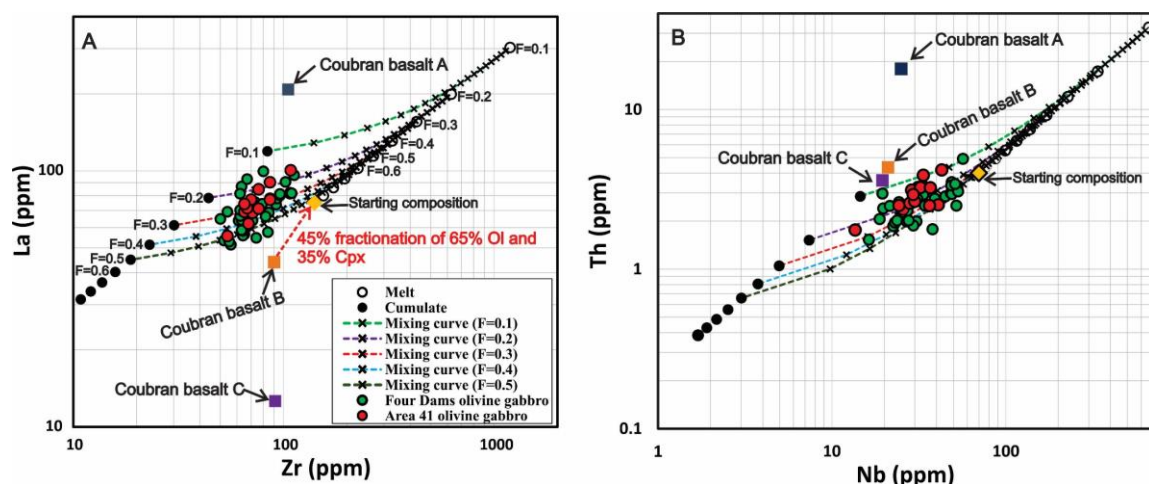

Figure 5-18. Geochemical model curves for La vs. Zr (A) and Th vs. Nb (B) for the olivine gabbro at Four Dams and Area 41. Black circles represent 100% instantaneous cumulates at different F , e.g., the $F=0.9$ beside the black circle represents the cumulate composition at this degree of fractionation and the black circle beside the $F=0.1$ label represent cumulate at this degree of fractionation. Similarly, the open circles represent residual melt compositions at F varying from 0.9 (lowermost) to 0.1 (uppermost). The dashed curve that connects the cumulate and residual melt (both at the same F) indicate composition of the rock with different proportions of cumulate and interstitial melt formed at this F . The crosses on the curves denote 5% of cumulates, or 5% increments of interstitial melts, from left to right. Thus, data points of rocks fall on, or between, curve(s) can be explained by mixtures of cumulates and interstitial melts at F of the starting liquid.

Table 5-8. Trace element compositions of different liquids, units are all in ppm.

	Type B Coubran basalts	$F=0.55$ of type B Coubran basalts	Possible starting composition	
Ba	398	700	680 (Four Dams)	6000 (Area 41)
Sr	450	785	785 (Four Dams)	2000 (Area 41)
Th	4.3	7.7		4
Nb	21	38		70
La	46	82		82
Zr	93	160		140

5.8.3 LILE

Barium and Sr are used to model the olivine gabbro at Area 41 and Four Dams. Partition coefficients of Ba and Sr into plagioclase ($D_{Ba}^{Pl}=0.60$, $D_{Sr}^{Pl}=3$) used in this study are from Villemant et al. (1981), these values are close to those calculated by using equations of Blundy and Wood (1991) (shown below) assuming that the average anorthite content of plagioclase is 50 (Fig. 5-9 and Table 5-3) and the

temperature is 1400 degrees kelvin. Note that the temperature used here is based on orthopyroxene-clinopyroxene geothermometer results from Shahabifar Far (2016).

$$RT \ln D_{Sr}^{Pl} = 26,800 - 26,700 * X_{An}$$

$$RT \ln D_{Ba}^{Pl} = 10,200 - 38,200 * X_{An}$$

where R is ideal gas constant (8.314 JK⁻¹mol⁻¹), T is the absolute magma temperature (kelvin), X_{An} is the mole fraction An of plagioclase.

5.8.3.1 Low Ba Olivine gabbro (Four Dams)

The observed negative correlation between anorthite content of plagioclase and Ba concentrations in plagioclase for the units from Four Dams (Fig. 5-10) suggests that Ba is an incompatible element in this system. Since there is a positive correlation between whole-rock Ba and Sr for units at Four Dams (Fig. 5-15F), it is expected that Sr is also an incompatible element in this system. However, the assumed Sr partition coefficient into plagioclase ($D_{Sr}^{Pl}=3.0$) is too high to have Sr with a bulk partition coefficient less than 1. Alternatively, the appropriate Sr vs. Zr model that accommodates both the incompatible behavior of Sr and the fit for data points, is created based on $D_{Sr}^{Pl}=1.3$. The lower partition coefficient may be reasonable (see Bedard, 2001). It is uncertain why D_{Sr}^{Pl} is smaller in this case; perhaps it indicates the Layered Series magma at Four Dams has a higher temperature than that at Area 41 according to the Sr equation of Blundy and Wood (1991). Models of Ba vs. Zr and Sr vs. Zr for the olivine gabbro rocks at Four Dams are displayed in Figures 5-19A and B. Note that these two fitted models require the possible parental magma at Four Dams contain 680 ppm Ba and 785 ppm Sr, close to those in F=0.55 residual melt of the type B Coubran basalts (after fractionation of 65% olivine and 35% clinopyroxene, Table 5-8).

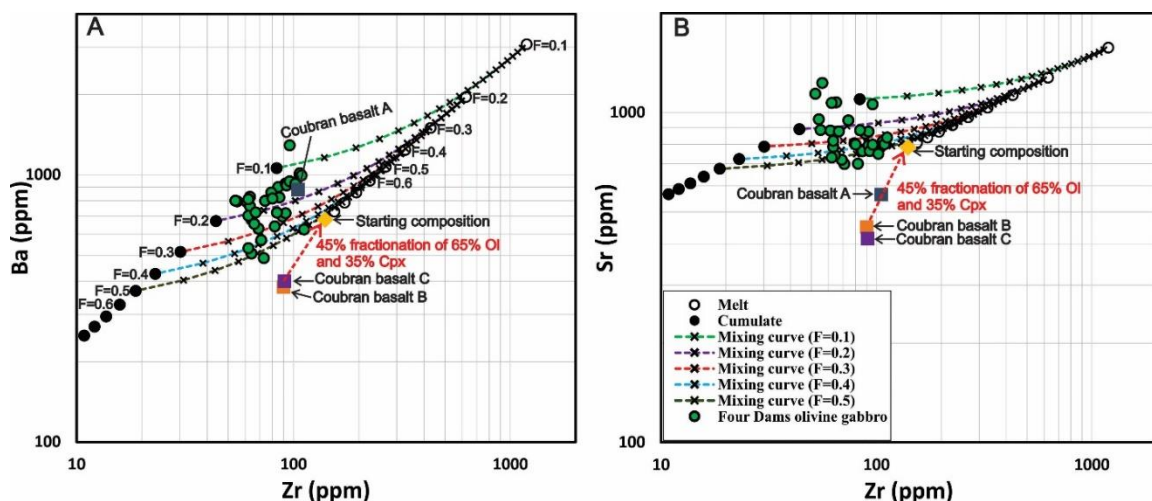

Figure 5-19. Geochemical model curves for Ba vs. Zr (A) and Sr vs. Zr (B) for the olivine gabbro at Four Dams. Black circles represent 100% instantaneous cumulates at different F , e.g., the $F=0.9$ beside the black circle represents the cumulate composition at this degree of fractionation and the black circle beside the $F=0.1$ label represent cumulate at this degree of fractionation. Similarly, the open circles represent residual melt compositions at F varying from 0.9 (lowermost) to 0.1 (uppermost). The dashed curve that connects the cumulate and residual melt (both at the same F) indicate composition of the rock with different proportions of cumulate and interstitial melt formed at this F . The crosses on the curves denote 5% of cumulates, or 5% increments of interstitial melts, from left to right. Thus, data points of rocks fall on, or between, curve(s) can be explained by mixtures of cumulates and interstitial melts at F of the starting liquid.

5.8.3.2 High Ba Olivine gabbro (Area 41)

There is good evidence suggesting that Ba is a compatible element during formation of the olivine gabbro at Area 41, including : 1) whole-rock La and Ba in olivine gabbro are negatively correlated (Fig. 5-15C); 2) the down-hole Ba profile has an opposite trend with down-hole La and Zr profiles (Fig. 5-7); and, 3) anorthite content of plagioclase and Ba concentrations in plagioclase are positively correlated (Fig. 5-10), indicating the residual melt becomes increasingly depleted in Ba during fractionation. Therefore, in order for Ba to have a bulk partition coefficient >1 , a Ba-rich phase such as orthoclase or biotite needs to be added to the fractionating phases. Note that adding several weight percent of either orthoclase or biotite onto the liquidus will have limited influence to the modeling scheme for HFSE as shown in section 5.8.2.

5.8.3.2.1 Orthoclase

According to petrography, 7 wt.% orthoclase is added onto the liquidus. Weight percent of other fractionating phases used when modeling HFSE is readjusted proportionally to make the total as 100%. To our knowledge, there are no Ba and Sr partition coefficients into orthoclase reported in any basaltic system. However, Table 5-5 shows that Ba and Sr contents in orthoclase for the Layered Series units at Area 41 are approximately 22 and 1.1 times, respectively, higher than those in plagioclase. Provided that orthoclase joined the plagioclase on liquidus, D_{Ba}^{Or} and D_{Sr}^{Or} can be reasonably deduced through multiplying D_{Ba}^{Pl} and D_{Sr}^{Pl} by factors of 22 and 1.1, respectively, which are around 13 and 3.3. Nevertheless, the lack of published Ba and Sr coefficients into orthoclase means that the Ba vs. Zr and Sr vs. Zr models (Figs. 5-20A and B) here are semi-quantitative. Note that fitted model curves in each case require that the possible parental magma contains around 6000 ppm Ba and 2000 ppm Sr (Table 5-8), respectively, to best explain the observed rock compositions. These values are significantly higher than Ba and Sr contents inferred for the Layered Series parental magma at Four Dams (680 ppm Ba, 785 ppm Sr, Fig. 5-19) and cannot be related to all three types of the Coubran basalts.

Figure 5-20. Geochemical model curves for Ba vs. Zr (A) and Sr vs. Zr (B) for the olivine gabbro rocks at Area 41 (assuming orthoclase is on liquidus). Black circles represent 100% instantaneous cumulates at different F , *e.g.*, the $F=0.9$ beside the black circle represents the cumulate composition at this degree of fractionation and the black circle beside the $F=0.1$ label represent cumulate at this degree of fractionation. Similarly, the open circles represent residual melt compositions at F varying from 0.9 (lowermost) to 0.1 (uppermost). The dashed curve that connects the cumulate and residual melt (both at the same F) indicate composition of the rock with different proportions of cumulate and interstitial melt formed at this F . The crosses on the curves denote 5% of cumulates, or 5% increments of interstitial melts, from left to right. Thus, data points of rocks fall on, or between, curve(s) can be explained by mixtures of cumulates and interstitial melts at F of the starting liquid.

5.8.3.2.2 Biotite

According to petrography, 5 wt.% biotite is added on liquidus in this case, and weight percent of other fractionating phases used in section 5.8.2 is readjusted proportionally to make the total as 100%. Note that Ba and Sr partition coefficients into biotite used in this case are 10 and 0.7, respectively, both values are from Villemant et al. (1981) determined in alkaline basalt system. Clearly, the Ba vs. Zr model (Fig. 5-21A) cannot explain the olivine gabbro samples at Area 41 and Ba also has a bulk partition coefficient <1 . By contrast, Sr vs. Zr model (Fig. 5-21B) in this case is similar to that produced when assuming orthoclase is on liquidus, which works well for the olivine gabbro samples at Area 41. Note that Ba and Sr contents in the possible parental magma at Area 41 in this case are 5200 ppm and 2000 ppm, respectively, close to those in the Layered Series parental magma when assuming

orthoclase is on liquidus. The high Ba and Sr contents cannot be related to any type of the Coubran basalts.

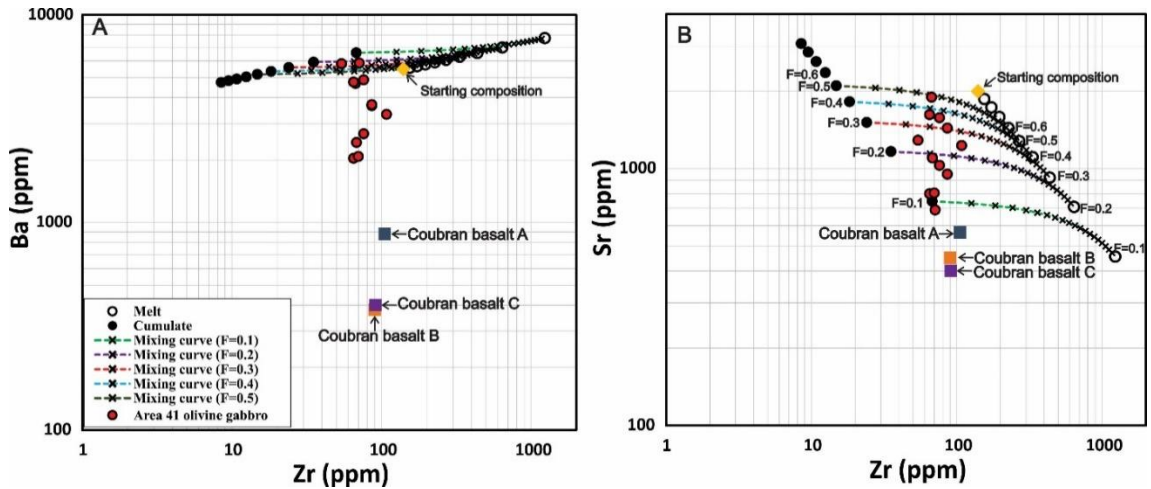

Figure 5-21. Geochemical model curves for Ba vs. Zr (A) and Sr vs. Zr (B) for the olivine gabbro rocks at Area 41 (assuming biotite is on liquidus). Black circles represent 100% instantaneous cumulates at different F , e.g., the $F=0.9$ beside the black circle represents the cumulate composition at this degree of fractionation and the black circle beside the $F=0.1$ label represent cumulate at this degree of fractionation. Similarly, the open circles represent residual melt compositions at F varying from 0.9 (lowermost) to 0.1 (uppermost). The dashed curve that connects the cumulate and residual melt (both at the same F) indicate composition of the rock with different proportions of cumulate and interstitial melt formed at this F . The crosses on the curves denote 5% of cumulates, or 5% increments of interstitial melts, from left to right. Thus, data points of rocks fall on, or between, curve(s) can be explained by mixtures of cumulates and interstitial melts at F of the starting liquid.

5.9 Discussion

5.9.1 The parental magma of the Layered Series

Figure 5-14 shows that the average Layered Series units have almost parallel REE profiles with the average Coubran basalts, indicating a potential co-genetic relationship between the two rock groups. The inspection of the parental magma composition through geochemical modeling by assuming the Rayleigh fractionation scenarios indicates that the Layered Series parental magma at Area 41 and Four Dams has similar La, Zr with $F=0.55$ residual melt of the type B Coubran basalts (after fractionation of 65% olivine and 35% clinopyroxene). This also applies to Ba and Sr contents at Four Dams, but not at Area 41. Ba and Sr contents in the parental magma at Area 41 are too high to be related to any type of Coubran basalts, and

possible reasons for this will be addressed in the following section. Shahabifar Far (2016) investigated the Coubran basalts in the MELTS program and found that the olivine and clinopyroxene are the first crystallization phases. This is consistent with the fractionation scheme as mentioned above. Thus, based on these observations, it seems that a fractionated Coubran basalt-like magma with considerably higher La, Zr, Ba, and Sr could be considered as a parental magma for the Layered Series. However, as mentioned in section 5.8.2, Nb and Th do not work. Therefore, it is more reasonable to assume that the parental magma for the Layered Series can not be related to the Coubran basalts, but may share some characteristics with magma that is compositionally similar to the type B Coubran basalts.

5.9.2 Insights from the behavior of Ba and Sr

5.9.2.1 Ba and Sr differences between the starting liquids 1 and 2

The range and inter-element ratios for trace element abundances at Four Dams are very similar to those at Area 41, except for Ba and Sr. The possible parental magma at Area 41 has higher Ba and Sr contents than that at Four Dams. One possibility for their Ba and Sr differences may be real variations of these elements in the same magma, as for the Wolfcamp lake basalts, which exhibit highly variable Ba and Sr contents (216-1444 ppm Ba, 320-860 ppm Sr) with tightly constrained major constituents (48-52 wt.% SiO₂, 1.88-2.05 wt.% TiO₂, 13.85-15.21 wt.% Al₂O₃, etc.) (Good, pers. commun., 2016). However, the fitted Ba vs. Zr model (Fig. 5-20A) predicts that the Layered Series magma at Area 41 has around 6000 ppm Ba and 2000 ppm Sr. To our knowledge, such a high Ba content is rarely reported for any alkaline basalt. Therefore, rather than natural variation of the same basalt, something special must have occurred. To fully interpret this is difficult, here we propose two possibilities. First, this difference may be related to the different degrees of partial melting of Ba-hosting phases (e.g., amphibole) in the upper mantle. Second, this difference can also be related to metasomatism whereby extra Ba and Sr contents were introduced into the Layered Series parental magma at Area 41 through the involvement of fluids. The second hypothesis may be more reasonable because: 1)

Ba and Sr are fluid-mobile elements; and, 2) the Layered Series rocks from Area 41 also contain higher concentrations in other fluid-mobile elements such as Rb, K, Cs than the Layered Series rocks from Four Dams (see Appendix 6).

5.9.2.2 Controlling phases of whole-rock Ba and Sr

It is reasonably certain that whole-rock Ba and Sr are mainly controlled by potassium-bearing phases in light of the positive relationships between Ba vs. K_2O , and Ba vs. Sr (Figs. 5-15E and F). Figures 5-16 and 5-17 show that the different Ba vs. K_2O and Ba vs. Sr trends between the units at Area 41 and Four Dams can be explained by their different mixing controls of minerals. For example, at Area 41 Ba and Sr are controlled by plagioclase, orthoclase, and biotite with proportions of 90:6:4, whereas at Four Dams they are only controlled by plagioclase and biotite with proportions of 90:10. The possible fractionation of orthoclase or biotite at Area 41 perhaps results in the compatible behaviour of Ba, this will be fully discussed in the following section.

It is noteworthy that in Ba vs. Sr diagram (Fig. 5-17) the oxide augite melatroctolite samples at Four Dams are generally located above the mixing control line that goes through its olivine gabbro counterparts. The higher Ba/Sr for the oxide augite melatroctolite at Four Dams can be explained by: 1) at Four Dams the oxide augite melatroctolite contains a higher amount of interstitial liquid (*e.g.*, biotite); and, 2) the oxide augite melatroctolite has higher biotite: plagioclase ratio than olivine gabbro, thus its whole-rock Ba and Sr have a more control by biotite. The first possibility may be reasonable given that Ba seems to be more incompatible than Sr in the magma system at Four Dams (see Table 5-7). However, it can be ruled out considering that the similar ranges of Zr contents (80-100 ppm) between the olivine gabbro and oxide augite melatroctolite at Four Dams (Figs. 5-6 and 5-13) suggest that they contain a similar amount of interstitial melt. Alternatively, the second explanation is consistent with lithogeochemical results that at Four Dams the oxide

augite melatroctolite contains similar K₂O contents with, and significantly lower Al₂O₃ contents than, the olivine gabbro (Fig. 5-13).

5.9.2.3 Is orthoclase or biotite on liquidus?

As mentioned earlier, there is ample evidence suggesting that Ba is a compatible element in the Layered Series magma at Area 41. However, the equation of Blundy and Wood (1991) predicts that D_{Ba}^{Pl} is around 0.6. Thus, in order for Ba to be compatible (bulk partition coefficient > 1), either orthoclase or biotite needs to be on liquidus. Orthoclase is favoured over biotite as a liquidus mineral for the following reasons: 1) biotite textures indicate that it typically crystallized very late, as an accessory mineral in the mafic magma system; 2) orthoclase appears to have crystallized earlier, as an interstitial phase; 3) orthoclase is more abundant than biotite in the units at Area 41; and, 4) orthoclase may have formed simultaneously with, or slightly later than, the plagioclase based on petrographic observation that wormy-like plagioclase is within the perthite that formed the myrmekite texture (Fig. 5-5A). Furthermore, given that biotite is on liquidus, the Ba vs. Zr model (Fig. 5-21A) poorly fit all olivine gabbro samples from Area 41, the fit can be even worse when considering that $D_{Ba}^{Bt}=10$ used in Figure 5-21A is likely overestimated because microprobe analyses of biotite and plagioclase in the Layered Series at Area 41 suggest D_{Ba}^{Bt} should be just 4.5 times of D_{Ba}^{Pl} (0.6) (Table 5-5). Alternatively, when considering orthoclase as a liquidus mineral, the fitted Ba vs. Zr and Sr vs. Zr models (Fig. 5-20) are produced based on $D_{Ba}^{Or}=13$ and $D_{Sr}^{Or}=3.4$, both are viable values deduced based on Ba and Sr contents in orthoclase and plagioclase (Table 5-5). The validity of Ba vs. Zr and Sr vs. Zr models when assuming orthoclase is on liquidus can be further tested using the following strategy: Figure 5-20 predicts that F=0.4 melt of the parental magma at Area 41 contains around 4000 ppm Ba and 970 ppm Sr, given that $D_{Ba}^{Pl}=0.6$ and $D_{Sr}^{Pl}=3.0$, 2400 ppm Ba and 2900 ppm Sr, respectively, in plagioclase are deduced, these are similar to Ba and Sr contents in plagioclase as determined by electron microprobe analyses (3000±390 ppm Ba, 2100±270 ppm Sr, Table 5-5).

However, although the Ba vs. Zr and Sr vs. Zr models by assuming orthoclase on liquidus seem to work from a geochemical perspective, it is still a challenge matter when considering the geological fact. Fractionating liquidus alkali feldspar more likely can occur in phonolites, minettes, and carbonatites which are of alkaline compositions (Zhang et al., 1993a; Deer et al., 2001; Azzone et al., 2009). Particularly, to our knowledge, no study ever reported orthoclase as a liquidus mineral in any basaltic magma system. Thus, in order to fully interpret this, it is necessary to investigate whether the Layered Series magma is still basaltic or not. The Coubran basalts contain around 50 wt.% SiO₂, it is reasonable to assume that the more evolved Layered Series parental magma contain > 50 wt.% SiO₂. The exact SiO₂ content in the parental magma is hard to quantify, but some insight can be gained from SiO₂ contents in the type B Coubran basalt (~50 wt.%). Geochemical modeling results show that the Layered Series parental magma likely has a similar composition with F=0.55 melt of the type B Coubran basalts (after fractionation of 65% olivine and 35% clinopyroxene). The F=0.55 melt of the type B Coubran basalts contains around 55 wt. % SiO₂ (partition coefficients used are: $D_{Si}^{Ol}=0.77$ (Beattie, 1994), $D_{Si}^{Cpx}=1.11$ (Vanwestrenen et al., 2000), and $D_{Si}^{Pl}=0.9$ (Bindeman and Davis, 2000)), this value may be close to SiO₂ content in the Layered Series parental magma. Apparently, a magma with 55 wt.% SiO₂ is nearly not basaltic (45-55 wt.% SiO₂ by the definition) and the later fractionated melts will tend to be andesitic or even syenitic. Under this condition, the orthoclase is possible to be on liquidus particularly in the later melts. If this is correct, it means that there might be a link between genesis of the Layered Series and the syenites during fractional crystallization of the basaltic magma at the Coldwell Alkaline Complex. This is a testable hypothesis and more work is needed to proof this, but at least we observed syenitic interstitial liquids in the Two Duck Lake gabbro at the Marathon deposit and also Mitchell et al. (1992) have ascribed the genesis of the syenites at the Coldwell Alkaline Complex to be the extensive fractional crystallization of mantle-derived basalt magma within the plutonic infrastructure of the complex.

5.9.3 Why is the Layered Series PGE barren?

As mentioned above, all known PGE mineralization at the Eastern Gabbro is solely related to the Marathon Series whereas the Layered Series lacks PGE mineralization (<0.005 ppm PGE). The Layered Series gabbro was proposed by Shaw (1997) to crystallize from an evolved, Fe-rich magma, its parental magma thus may be the result of a low degree partial melting of upper mantle (Mungall and Naldrett, 2008). Given this hypothesis, it is reasonable to assume that most of refractory sulfides that are main hosts to PGE elements were retained in the mantle, thus resulted in the poor PGE contents in the generated magma. However, as interpreted in section 5.9.1, the Layered Series magma, although is highly fractionated indeed, share some characteristics with magma that is compositionally similar with the type B Coubran basalts. The origin of the Coubran basalts is poorly constrained due to its very unusual geochemical composition, but there is geochemical evidence, *e.g.*, similar Ce/Y and Nb/Zr trends, suggesting that the Coubran basalts are co-genetic with the Marathon Series Two Duck Lake gabbro (Cundari, 2012). Thus, it is more reasonable to assume that the PGE-poor nature of the Layered Series magma is not related to the source. Alternatively, it is more likely related to processes during magma evolution.

Sulfide saturation prior to the generation of the Layered Series units is another hypothesis to explain the lack of PGE mineralization in the Layered Series. Due to high partition coefficients of PGE elements into sulfide minerals, this earlier sulfide saturation will inevitably drive the residual magma to become PGE depleted. Modeling variations of sulfur contents in residual liquids is a direct way to assess the potential sulfide saturation. Unfortunately, the sulfur contents of the Coubran basalts are not known, and thus sulfur saturation cannot be modelled. However, this process can be envisaged given that the Layered Series parental magma is more evolved than the Coubran basalts, but the former contains lower PGE (<0.005 ppm PGE) than the latter (0.01 ppm Pt and 0.01 ppm Pd). Furthermore, two Cu-rich

mineralization zones located at the top and bottom of bore hole FD-13-34 at Four Dams were described in Chapter 3. The top mineralization zone is within the Layered Series and lacks PGE mineralization (~2000 ppm Cu and <0.005 ppm PGE) whereas the bottom mineralization zone is within the Marathon Series and is relatively PGE-enriched (~2800 ppm Cu, 0.1 ppm Pt, and 0.18 ppm Pd). Note that the inspection of drill cores at Four Dams shows that the top Cu-rich and PGE-barren mineralization zone extends along strike for several hundred meters. The extremely high Cu/Pd for the top sulfide mineralization zone is a good indicative of PGE depletion as a result of earlier sulfide saturation. In addition, as will be explained below, the Layered Series magma may have undergone an undercooling process. The undercooling is favorable for inducing the separation of an immiscible sulfide melt through lowering down the sulfur solubility in the silicate magma (Li et al, 2001). Therefore, it is reasonable to assume that an earlier event of sulfide segregation occurred prior to the development of the Layered Series gabbro, which is responsible for the lacking PGE mineralization in the Layered Series. A similar example of sulfide segregation in the Midcontinent rift system is related to the Sonju Lake Intrusion (SLI) of the Duluth Complex, as proposed earlier by Miller (1999) and later confirmed by Li and Ripley (2005), the SLI intrusion reached sulfide saturation when magnetite joins plagioclase and clinopyroxene as a liquidus phase before ~60% fractional crystallization.

5.9.4 Evidence for multiple intrusions

5.9.4.1 Insights from the olivine-clinopyroxene Fe/Mg disequilibrium

Figure 5-15 shows that the olivine and clinopyroxene in the units at Area 41 and Four Dams have variable Fe/Mg exchange coefficients, similar to observations of Good (1992) for the Two Duck Lake gabbro at the Marathon deposit. The variable Fe/Mg exchange coefficient is not consistent with what is expected for this coefficient (constant) when olivine and clinopyroxene are in chemical equilibrium during magma fractionation at a certain temperature, reflecting something unusual happened that interfered the chemical equilibrium between the two phases. There

are also other evidence suggesting this disequilibrium, including: 1) the resorption of olivine by clinopyroxene (Fig. 5-4C); and, 2) the disparity between variation ranges of Mg#s of olivine and clinopyroxene particularly for the units at Area 41 (Fig. 5-9). Further, the units at Area 41 and Four Dams present different down-hole trends in olivine-clinopyroxene Fe/Mg exchange coefficients, suggesting that different processes occurred for the Layered Series magma at the two areas.

Good (1992) related the deflection of olivine-clinopyroxene Fe/Mg exchange at the base of the Two Duck Lake gabbro to the migration of partial melt and stratigraphically higher up in the intrusion to the collection of residual interstitial melt (granophyre). This, however, may not apply to the disequilibrium in this case because: 1) granophyric textures are never observed in the Layered Series units in this study; and, 2) tight ranges of whole-rock La and Zr (80-110 ppm La, 70-100 ppm Zr, Figs. 5-6 and 7) suggest that units contain similar amounts of interstitial melts. Two alternatives are proposed here. First, the olivine-clinopyroxene Fe/Mg disequilibrium can be a result of the mixing of olivine and clinopyroxene crystals from magma at different stages of evolution. This can occur in a dynamic magma chamber which was replenished by pulses of magma intrusions. Under this circumstance, early formed crystals were easily disturbed by the inflowing magmas, particularly when they were gravitationally unstable and underwent a slumping process. Second, Latypov (2015) suggested that the magma undercooling can result in the chemical disequilibrium between mineral phases. Loucks (1996a) also suggested that the cooling would result in short- range diffusive exchange and alter Mg#s of olivine and clinopyroxene to different extents, i.e., greater for olivine. If this is the case, then different Fe/Mg down-hole profiles between the units at Area 41 and Four Dams imply that they had undergone undercooling but in different manners at the two areas. Since the Fe/Mg exchange between olivine and clinopyroxene is inversely related to the magma temperature (Loucks, 1996a, b), the up-hole increase in the olivine-clinopyroxene exchange coefficient for the units at

Area 41 can be explained by an increase in the extent of magma undercooling. Conversely, the trend for the units at Four Dams can be attributed to a decrease in the degree of magma undercooling. It is, however, difficult to imagine that the two styles of magma undercooling can occur for a single magma intrusion en route. Instead, it is more likely associated with a magma conduit system where inflowing melts underwent different degrees of undercooling when passing through the conduit. Therefore, no matter under which scenario, the olivine-clinopyroxene Fe/Mg disequilibrium indicates a dynamic magma conduit system whereby the Layered Series formed by multiple intrusions. This is also consistent with the observed down-hole step-like/zig-zag variations in incompatible elements and ratios for the Layered Series at Area 41 and Four Dams (Figs. 5-6 and 7).

5.9.4.2 Insights from La/Sm and Gd/Yb

As mentioned in section 5.5.1, the olivine gabbro at Four Dams can be subdivided into four subgroups (olivine gabbro I-IV). Each sub unit has different values and down-hole variations of La/Sm and Gd/Yb. Since the REE are controlled to some extent by apatite, and partitioning of Sm and Gd into apatite is greater than for La and Yb, respectively (Paster et al., 1974), it is expected that La/Sm should increase whereas Gd/Yb should decrease with increasing apatite. However, this is not the case here because P_2O_5 in these sub units are nearly constant (Fig. 5-6), thus their systematic and clearly defined fluctuations of La/Sm and Gd/Yb must be a result of multiple intrusions with slightly different magma compositions, regardless of the amount of interstitial melt.

5.9.5 Magma reversal trends

The Mg#s of olivine and clinopyroxene, and the anorthite content of plagioclase grains in the Layered Series units at Area 41, decrease slightly with depth from beginning down to ~ 10m, generally become increasingly primitive downward (Fig. 5-7), suggesting a normal mineral compositional trend, except at the top of the hole. It is thus surprising that whole-rock incompatible elements such as La and Zr also generally increase with depth, and also there is a positive correlation between Mg#

of olivine and whole-rock La (Fig. 5-22). This is contradictory to what is expected for fractional crystallization, *i.e.*, the whole-rock La and Zr trends for the Layered Series at Area 41 are reversed. Therefore, the Layered Series at Area 41 is characterized by the normal fractionation in mineral chemistry and the reverse differentiation in whole-rock trace elements.

The Layered Series units from Four Dams show significantly different profiles with those from Area 41. Specifically, the upper oxide augite melatroctolite has nearly constant mineral chemical compositions and highly variable whole-rock compositions. The olivine gabbro can be subdivided into four subgroups. Each individual subgroup has a reverse trend in La, Zr (Fig. 5-6), and based on the general variation scheme of mineral chemistry, it also likely has a reverse mineral compositional trend that cannot be fully resolved by the current sampling density. The bottom oxide augite melatroctolite presents a reverse trend in whole-rock La. Since the oxide augite melatroctolite and the olivine gabbro essentially are the same unit, and here only the olivine gabbro package presents well developed magma reversal trends in both whole-rock and mineral chemical compositions, we thus focused on the olivine gabbro package to interpret the magma evolution at Four Dams.

Figure 5-22. Relationship between Mg# of olivine and whole-rock La for olivine gabbro from Area 41 (red) and Four Dams (green). Note that the olivine gabbro at Four Dams does not necessarily have a negative trend and could also be considered as clusters. The important point is that the trend is clearly different than that for Area 41.

Shaw (1997) also observed both the normal and reverse mineral compositional trends in the Layered Series of Bamboos and Highway traverses (Figure 5-1) and suggested that its origin was uncertain, but might be related to either a trapped liquid effect, the assimilation of Archean footwall rocks, or the successive injections of more primitive magma. Reverse compositional trends are commonly observed in silicate layers in layered intrusions (Eales et al., 1990). Notable examples include the Insizwa complex of Transkei (Lightfoot and Naldrett, 1984), Duluth Complex of Minnesota (Miller and Ripley, 1996), and Fongen-Hyllingen intrusion of Norway (Egorova and Latypov, 2012b). Many different mechanisms have been proposed to explain compositional magma reversals, but none of them provide an entirely satisfactory explanation. Latypov (2015) comprehensively reviewed the current models for two types of reverse compositional profiles including coupled whole-rock and mineral compositional trends and decoupled whole-rock and mineral compositional trends, both of which are observed in this study, *e.g.*, the decoupled magma reversal at Area 41 and the coupled magma reversal at Four Dams.

A decoupled trend is where the whole-rock trend is reversed but the mineral compositional trend is normal. Latypov (2015) attribute this to an upward decrease in the amount of trapped melt in the rocks. As a result, rocks tend to contain decreasing abundances of incompatible elements upward, whereas their mineral compositional variations may still behave in a normal trend. However, this hypothesis cannot explain the decoupled magma reverse for the Layered Series units at Area 41 because all samples contain similar amounts of interstitial liquids based on their tight ranges of La and Zr abundances (Fig. 5-7). Thus, an alternative process must have resulted in the decoupled trends at this location. To investigate this, geochemical model of La vs. Zr for a subset of samples at Area 41 that have both whole-rock and mineral chemical analyses was created (Fig. 5-23). In addition, Mg# of olivine for these samples is indicated in this model for comparisons. It shows that the more primitive rocks trapped the more evolved liquids. This is not consistent with the classical fractional crystallization model, and may indicate that the interstitial liquid system was completely overturned. If this is correct, it means that the fractionated cumulate piles have trapped other stages of interstitial liquids and there is no chemical equilibrium established between the two. Perhaps the observed local resorption of plagioclase by biotite in Area 41 olivine gabbro (Fig. 5-4D) reflects this disequilibrium. The convection of interstitial liquids can be resulted by numerous factors including thermal convection (Turner, 1979), gas-driven (Ruprecht et al., 2008), or compaction (McBirney, 1995; Mathez et al., 1997). For example, McBirney (1995) attributed the enrichment of the Upper Border Series of the Skaergaard Intrusion to the rise of compaction-released liquids from the floor. Since the Layered Series units were developed by multiple intrusions (see section 5.9.4), the overall normal mineral compositional trend for units at Area 41 may indicate that the successively replenished magma became increasingly fractionated. Note that the down-hole olivine-clinopyroxene trend at Area 41, as explained in 5.9.4.2, indicates the Layered Series magma at Area 41 may have undergone a gradual increase in the degree of magma undercooling. If this is correct, the

inflowing magma would become increasingly fractionated after passing through the conduit (Latypov, 2015). Alternatively, the normal mineral chemical trend can also be produced when the rate of magma recharge is lower than the rate of magma crystallization. Under this circumstance, the generic evolution of the magma chamber was largely dependent on fractionation of the earlier pulses of magma.

Figure 5-23. La vs. Zr model for a subset of the olivine gabbro (red infilled circles) from Area 41. Numbers beside each sample are Mg# of olivine. The observed Mg# do not match the predicted Mg# based on this model.

Since the units at Four Dams may have formed by multiple intrusions, one possible explanation to the coupled magma reversal (whole-rock compositions decrease upward and mineral chemical compositions increase upward) is related to successive injections of magma that is progressively more primitive. This is consistent with the scenario that the Layered Series magma at Four Dams underwent a gradual decrease in the degree of magma undercooling (see section 5.9.4.2) because: 1) decreasing the degree of undercooling will fractionate more primitive

minerals (Latypov, 2015); and, 2) this scenario implies that the conduit was increasingly heated, which can result in a gradual decrease in the degree of earlier fractional crystallization during magma flowing in the conduit. Note that the second reason also explains the whole-rock compositional reverse in this case. Another possible explanation to this coupled magma reversal is related to the rate of magma recharge and magma crystallization, i.e., the rate of magma recharge > the rate of magma crystallization. Under this circumstance, the preceding fractionated residual liquids will have progressively decreasing roles in dilution of later injected magma and the overall consequence is to make the chamber become increasingly condensed.

5.9.6 Evidence for crystal sorting

As first mentioned in section 5.5.2, the down-hole mineral chemical profiles and similar REE distribution patterns indicate that the olivine gabbro and oxide augite melatroctolite are the same unit. The differences in mineral abundances between the two units (particularly magnetite) are considered as a result of crystal sorting. This sorting process is supported by the experimental work of Forien et al. (2015) who demonstrated that during the slumping of semi-consolidated cumulates the smaller and dense magnetite tend to be separated from the larger and less dense plagioclase. In addition, there is other evidence suggesting a crystal sorting process occurred during the generation of the Layered Series. First, the observed chemical disequilibrium between olivine and clinopyroxene, as mentioned in section 5.9.4, can be explained by a crystal sorting process whereby olivine and clinopyroxene from different stages of crystallization were mixed up. Second, Figure 5-14 shows that the oxide augite melatroctolite contains slightly higher abundances of REE than olivine gabbro. This can be interpreted by: 1) oxide augite melatroctolite is more evolved than olivine gabbro; 2) oxide augite melatroctolite contains a higher proportion of interstitial melt; and, 3) oxide augite melatroctolite contains more apatite than olivine gabbro because REE is mainly controlled by apatite (Fig. 5-15A). The first two interpretations are easily ruled out because mineral chemical results (Fig. 5-9) shows that oxide augite melatroctolite has slightly higher Mg#s of

olivine and clinopyroxene than the olivine gabbro, and the similar ranges of Zr (Fig. 5-6) mean both units contain similar proportions of interstitial melts. Thus, this can only be explained by a high amount of apatite in the oxide augite melatroctolite. Realizing this is important because apatite is denser than plagioclase and will be sorted with clinopyroxene and olivine under the crystal sorting. Therefore, higher apatite and REE are consistent with mechanical sorting to form the oxide melatroctolite. In addition, this inference is more consistent with a model that has apatite as a cumulus phase, i.e., apatite does not crystalize in-situ.

5.9.7 Development of the Layered Series gabbro

It is possible to build a model to explain the observations as being the result of physical processes in a dynamic magma chamber. Based on characteristics of the Layered Series units and related interpretations, the development of the Layered Series gabbro is proposed to occur by multiple intrusions. Figure 5-24 illustrates the processes for formation of the Layered Series units, full details are given below.

Magma chambers at Four Dams and Area 41 were successively infilled by multiple pulses of the magma. The inflowing magma at Area 41 and Four Dams underwent some different processes. For example, at Area 41 the inflowing magma may either have progressively decreasing recharge rates, or have undergone a progressive increase in degrees of both magma undercooling and earlier fractional crystallization when it passed through the deep conduit. By contrast, at Four Dams the chamber was successively replenished by either progressively increasing amounts of magma, or by magma that underwent a gradual decrease in degrees of both magma undercooling and earlier fractional crystallization in the conduit. As interpreted in section 5.9.5, these provide explanations to the observed normal and reverse mineral compositional trends at Area 41 and Four Dams, respectively. When intruded magma cooled down from the walls of chambers at both areas, RFC governed the magma differentiation, which allowed crystals to be separated from the magma and the magma to evolve along the model curves. The crystallization

phases dominantly are plagioclase, olivine, and clinopyroxene, with minor amounts of apatite. Moreover, the compatible behavior for Ba for the Layered Series at Area 41 suggests that the magma at Area 41 also fractionated some orthoclase.

As the chamber was successively replenished and crystallization progressed, an increasing amount of crystalline materials were accumulated on the walls of the chamber. Gravity modeling (Mitchell et al., 1993) suggests that the eastern contact of the Eastern Gabbro is vertical to sub-vertical and generally shallows at depth. Our longitudinal sections (not shown) also indicate the contact of the Eastern Gabbro is nearly sub-vertical ($>45^\circ$). Therefore, at some points crystal accumulations plus trapped liquids on the walls became gravitationally unstable and slumped down the chamber wall. This has also been proposed by Shaw (1997). The slumping of semi-consolidated cumulates allowed the creation of turbidity currents as well as the physical sorting of crystals by their densities and sizes. The consequences of this is the generation of two types of Layered Series units consisting of the olivine gabbro and oxide augite melatroctolite, as well as the development of scours, cross stratification and locally planar layering. After crystal slumping, the system was closed, the sorted crystal pile was compacted and the trapped liquids continued to cool and crystallized biotite and other interstitial minerals in situ. The final result is the formation of the Layered Series rocks as observed at the Eastern Gabbro.

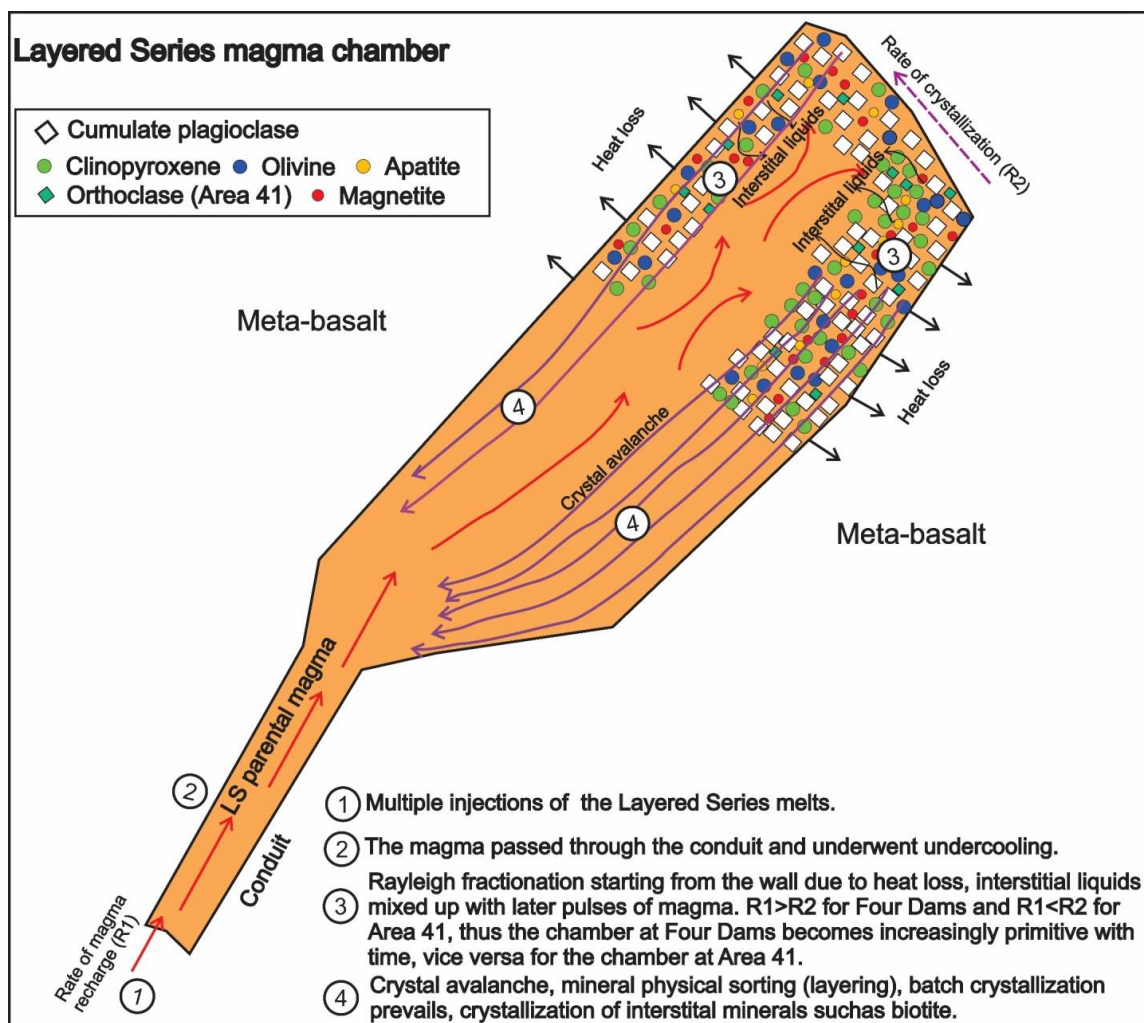

Figure 5-24. Schematic model showing the emplacement of the starting liquid for the Layered Series, the followed magma fractionation, crystal slumping, the development of the Layered Series rocks at Area 41 and Four Dams. See texts for full descriptions.

5.10 Conclusions

This contribution integrates petrography, whole-rock and mineral chemistry, geochemical modeling to comprehensively characterize the Layered Series at the Eastern Gabbro. Important conclusions are summarized as follows.

- (1) The parental magma of the Layered Series units is not related to the Coubran basalts, but may share some characteristics with the type B Coubran basalt.
- (2) The lack of PGE mineralization for the Layered Series is likely resulted by an early sulfide saturation.

- (3) The Layered Series magma perhaps is no longer basaltic, and the late melt tends to be syenitic, which crystallized orthoclase on liquidus. This introduces a testable hypothesis regarding the potential connection between the genesis of the Layered Series and the syenites during fractionation of the basaltic magma.
- (4) The geochemical magma reversal for the Layered Series at Area 41 is interpreted to be due to the convection of interstitial liquids. The coupled mineral and whole-rock compositional magma reversal for the Layered Series at Four Dams is interpreted to be related to multiple injections of magma that either has a progressively greater recharge rate, or underwent a gradual decrease in degrees of both magma undercooling and earlier fractional crystallization when the inflowing magma passed through the conduit.
- (5) The Layered Series units formed by multiple intrusions within a conduit system. The crystallization of minerals was governed by Rayleigh fractional crystallization. The slumping of accumulated crystal piles on the walls of chambers generated the layering as well as the formation of olivine gabbro and oxide augite melatroctolite through a crystal physical sorting process.

Chapter 6

Igneous stratigraphy and Cu-Pd mineralization at Area 41 within the Eastern Gabbro, Coldwell Alkaline Complex, Canada

1. Western University, London, ON, Canada

2. The University of Windsor, Windsor, ON, Canada

6.1 Introduction

The Coldwell Alkaline Complex is an ideal site for studying PGE mineralization because: 1) it is host to several zones of PGE-enriched mineralization; 2) the geology of the Coldwell Alkaline Complex is well understood through decades of exploration and research; 3) a large database of over 40000 assays from over 750 drill holes is available for testing hypotheses and generating interpretations for this complex; and, 4) the igneous rocks of the complex are relatively unaltered and undeformed, offering a good opportunity to study the magmatic processes and associated mineralization. A general model for PGE exploration at the Coldwell Alkaline Complex is needed. A study of Area 41 and a comparison with the Marathon deposit to evaluate whether the different zones of mineralization are related will contribute to the development of this general model.

Area 41 is a zone of Cu-PGE mineralization, located approximately 18 km north-east of the Marathon Cu-Pd deposit, the largest deposit within the Coldwell Alkaline Complex. The Marathon deposit has been well characterized by studies of Good and Crocket (1994), Ruthart (2013), and Good et al. (2015). However, Area 41 has not received any studies since it was discovered in 2006. Generally, there are three questions that need to be tested in order to build a model for the origin of Cu-Pd

mineralization at Area 41 and investigate its relationship with the Marathon deposit. First, the Eastern Gabbro suite at the Marathon deposit involves three lithological and geochemically distinct series: the meta-basalt, the Layered Series, and the Marathon Series. The rock types of the Eastern Gabbro suite at Area 41 need to be established and compared to those at the Marathon deposit to evaluate whether the litho- and chemostratigraphy at Area 41 is similar to the Marathon deposit. Second, the Cu-Pd mineralization at the Marathon deposit is only hosted by the Marathon Series, it is unclear whether mineralization at Area 41 is also hosted solely by the Marathon Series. Third, the origin of PGE mineralization at the Marathon deposit has been attributed by Good et al. (2015) to be related to orthomagmatic processes in a conduit setting, it is unclear whether Area 41 is also a conduit system. Testing these three questions can help develop guidelines for continued mineral exploration at the Coldwell Alkaline Complex, particularly knowing whether Area 41 mineralization is conduit-related, which is favorable for high grade PGE deposits (Naldrett et al., 1995; Naldrett and Lightfoot, 1999).

In this study, drill core logging, petrography and lithogeochemistry are used to establish the igneous stratigraphy at Area 41. Stillwater Canada Inc. exploration assay data are used to identify platinum-group elements (PGE) mineralization horizons and investigate their relationships with the igneous stratigraphy. Platinum-group mineralogy (PGM) and the effects of any post-magmatic hydrothermal activity will be characterized. 3D modeling is then used to evaluate whether the depositional setting of the mineralization at Area 41 is similar to the Marathon deposit.

6.2 Sampling and analytical methods

Representative powdered samples and rock slabs were collected from 5 drill holes. These drill holes intersect a complete igneous sequence of the Eastern Gabbro Suite, including the meta-basalt, the Layered Series and the Marathon Series. Drilling parameters for these drill holes are listed in Table 6-1.

Table 6-1. Parameters of sampled drill holes at Area 41.

DDH Number	Azimuth	Collar	Total Depth/m
SL-13-32	19.61	-85.28	252
SL-13-34	19.56	-80	201
SL-13-36	22.07	-44.59	228
SL-13-37	20.42	-80	261
SL-13-41	18.36	-80.05	291

Powdered samples were collected by grinding 1 m long channels (approximately 2 mm wide and 1 cm deep) along the drill core using a Thermo Scientific portable grinder. Between every two samples there is a rough 4.5 m gap without grinding. All powdered samples were loaded into PREM-4331 XRF sample cups capped with 4- μ m PREM-F2540 XRF sample cup films for pXRF whole-rock analysis first. The pXRF instrument used in this study is a Niton XL3t+ GOLDD+ pXRF analyzer that is equipped with a SDD, a high energy, and 50kV X-ray tube. Details of the analytical strategies and QA/QC control for pXRF analyses are given in Chapter 2, and the pXRF results are given in Table 6-2. A subset of representative powdered samples was selected after the inspection of pXRF results, which was then pulverized and sent to ALS Mineral Divisions in Thunder Bay for more accurate and precise lithogeochemical analysis. This analysis allows the evaluation of pXRF data quality, as well as the examination of rock forming mechanisms. Major elements were analyzed by lithium borate fusion with inductively coupled plasma (ICP)-atomic emission spectroscopy (AES) on a minimum 2 g of pulp samples. Trace elements were analyzed by lithium borate fusion and ICP-mass spectroscopy (MS) on 2 g of sample. Total S was analyzed using a Leco furnace on 1 g of sample. Ferrous Fe was analyzed by H₂SO₄-HF acid digestion and titration on 1 g of sample. Quality-control was conducted based on ALS Chemex quality-control procedures which involve analyses on a wide array of standards, blanks, and duplicates after each batch of samples. Average lab-based whole-rock major and trace element compositions for geologic units are summarized in Table 6-3. In addition, two

different data sets were also prepared, including Stillwater Canada Inc. exploration assays of Cu, S, Ni, Au, Pt, Pd down all included drill holes and 8 high precision S, Se, Pt, Pd, Au, Os, Ru, Ir, and Rh analyses down the PGE-enriched horizon in SL-13-36 (Table 6-4). The exploration assay data were determined on continuous 2 m sample intervals, and the other data set was collected from eight 2-m-thick, high-grade PGE intervals at drill hole SL-13-36. Both data sets were analyzed at ALS Thunder, Ontario, by fire assay and mass spectrometer finish (FAMS).

Polished thin sections representative of different gabbro units were prepared from selected drill holes at an interval between 5 and 20 meters. After petrographic examination, thin sections were carbon coated for mineral chemical analyses. Two sets of mineral chemical data were collected, including semi-quantitative and standardless analysis using benchtop scanning electron microscopy equipped with energy dispersive spectroscopy (bSEM-EDS) and standardized analysis using electron microprobe. The bSEM-EDS allows the acquisition of a large dataset that can be used for mapping igneous stratigraphy with low costs and high efficiency. The equipment used is a JEOL JCM-6000 Neoscope equipped with a JEOL JED-2300 energy dispersive X-ray analyzer at Western University. Analyses were conducted using 15 kV accelerating voltage, a high probe current, a 19 mm working distance, a 30-40 μm beam size, and standardless ZAF corrections. The analytical precision of bSEM-EDS analyses has been evaluated in Chapter 3, and bSEM-EDS results are given in Table 6-5. A subset of representative carbon-coated thin sections was chosen for electron microprobe analysis using a JEOL JXA-8530F field emission probe at Western University. The purpose of electron microprobe analysis is to validate of bSEM-EDS data quality, and acquire major and minor elemental compositions for minerals of interest (olivine, plagioclase, clinopyroxene, etc.). Analyses were conducted using a 15 kV, 20 nA beam. The beam was focused to a 1 μm spot for analyzing olivine and clinopyroxene, and to a 5 μm spot for analysing plagioclase. The peak counting time was 30 s for all elements and background

counts were a total of 30 s. A variety of synthetic and natural standards (Table 4-3 in Chapter 4) were used to calibrate different elements during probe analyses. The analytical precision for probe analyses has been evaluated in Chapter 3.

Table 6-2. pXRF analyses for mapped elements down two representative Area 41 drill holes. LOD means limit of detection.

6.3 Regional geology

The Proterozoic Coldwell Alkaline Complex is a sub-circular intrusion that has a diameter of approximately 25 km and a surface area of 580 km² and is the largest alkaline intrusive complex in North America (Walker et al., 1993; Shaw, 1997). It intruded the Archean Shreiber-Hemlo greenstone belt along the northern edge of the Midcontinent rift at 1108-1094 Ma, which marked the beginning of the main stage of magmatism related to the Midcontinent system (Walker et al., 1993; Heaman et al., 2007; Good et al., 2015). Petrologic and field studies conducted by Puskas (1970), Mitchell and Platt (1978, 1982), Mitchell et al. (1993), and Shaw (1997) recognized three superimposed intrusive centers constituting this complex, from east to west, they are center I, center II, and center III (Fig. 6-1). Paleomagnetic work conducted by Ashley and Kerns (2012) suggests that Centers I and III are the same age but both are older than Center II. Center I forms the eastern margin of the Coldwell Alkaline Complex, and is composed by the Eastern Gabbro, the Western

Gabbro, amphibole quartz syenite, iron-rich augite syenite, and mafic volcanic and subvolcanic rocks (Walker et al., 1993; Shaw, 1994; Good et al., 2015). Center II consists of alkali gabbro and syenite (Mitchell and Platt, 1978, 1982; Mulja, 1989). Center III is mainly composed of syenite and quartz syenite which are intrusive into most other phases of the complex and exhibit various degrees of crustal contamination (McLaughlin and Mitchell, 1989). It was proposed by Mitchell and Platt (1977, 1978) and Walker et al. (1993) that the emplacement of most rock units in the Coldwell Alkaline Complex was controlled by the faulting during cauldron subsidence at a subvolcanic depth.

6.4 Geology of Area 41

The Area 41 occurrence is situated near Sally Lake at the north east margin of the Eastern Gabbro (Fig. 6-1). The mineralization zone strikes east-southeast, dips at 45-50 degrees south and extends for over 1.2 km along strike. The geology of Area 41 is complex due to the intrusive crosscutting relationships, the complicated nature of the basal contact with the partially melted Archean rocks, and also the presence of some block faults. Geology and igneous stratigraphy of this property are depicted in Figures 6-2 and 6-3.

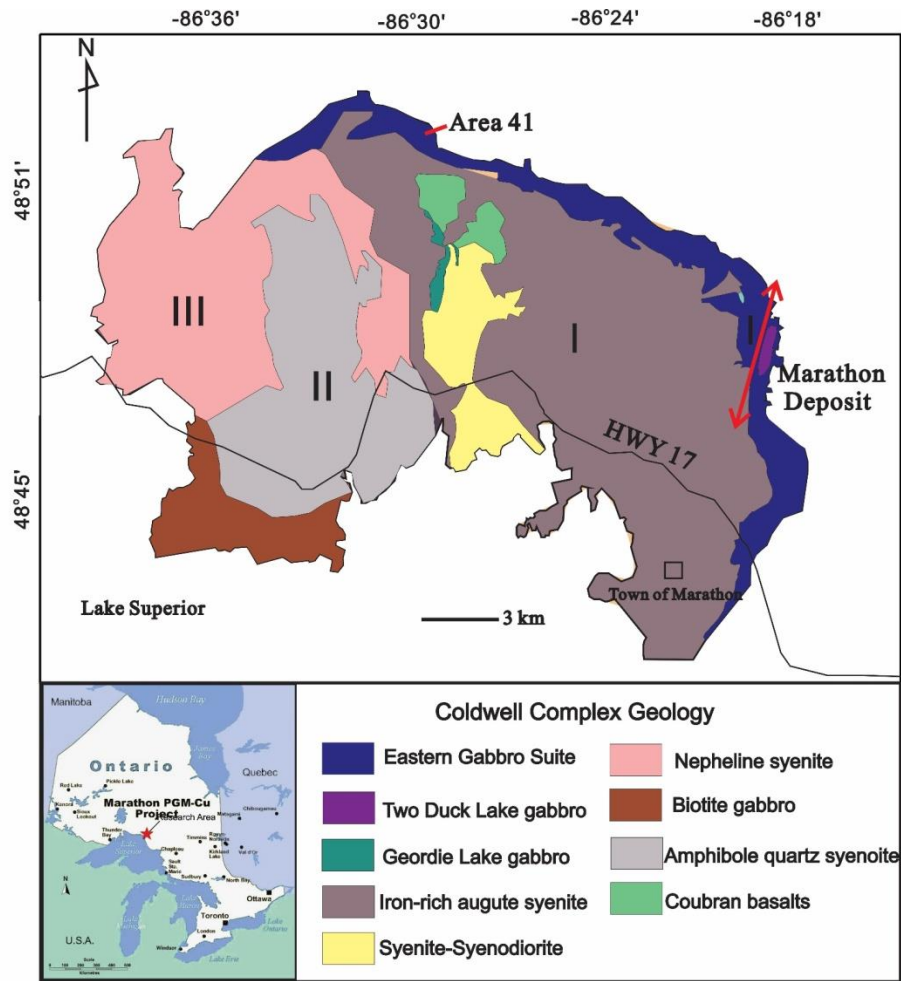

Figure 6-1. Geological map of the Coldwell alkaline complex, situated on the northern shore of Lake Superior (modified after Walker et al., 1993)., the location of Area 41 is represented as the red dot. The intrusive centers have been shown by Roman numerals (modified after Mulja and Mitchell, 1991).

6.4.1 Footwall contact

The footwall of Area 41 typically sits stratigraphically below ophitic gabbro of the Marathon Series with a variable or undetermined dip and thickness. Its mineral composition varies significantly but generally include three different rock types, from east to west: Archean granitoid rocks, metasediments, and rheomorphic intrusive breccia (Fig. 6-2). All three types of footwall rocks have undergone pyroxene hornfels metamorphism to local partial melting resulted by the heat from intrusions of the Eastern Gabbro (Currie, 1980). The ophitic gabbro crosscuts the footwall and has an igneous contact. The contact between granitoid footwall and the

ophitic gabbro strikes nearly NW-SE for a distance of around 1 km (Fig. 6-2). The rheomorphic intrusive breccia and/or gabbro contact at Area 41 is complicated because some blocks of rheomorphic intrusive breccia occur at the footwall underlain by the Archean granitoid rocks whereas others occur as xenoliths within the Marathon Series and (Fig. 6-3). An outcrop of rheomorphic intrusive breccia is shown in Figure 6-4A.

6.4.2 Meta-basalt

The meta-basalt at Area 41 makes up approximately 20 % of the total Eastern Gabbro package, similar to the proportion of the meta-basalt at the Marathon deposit as estimated by Good et al. (2015). At Area 41, the meta-basalt is exposed northwest of the mineralization at the surface and stratigraphically occurs close to the base of the Eastern Gabbro (Fig. 6-3). Locally the meta-basalt is intruded by numerous thin dykes of ophitic gabbro (Fig. 6-4B), which obscures its textures and features. The mineral composition of meta-basalt varies from basalt to olivine basalt, and consists of equigranular fine grained subhedral clinopyroxene, olivine, magnetite with interstitial plagioclase. Layering of this unit is weak and can be detected at the meter scale by gradational change in grain size, and locally by thin magnetite-rich horizons. A common texture for the meta-basalt unit is 120° angles of boundaries between crystals (granoblastic texture, Fig. 6-5A), which is interpreted by Good et al. (2015) as a result of pyroxene hornfels metamorphism. In addition, the formation of 1-2 cm sized zoned amoeboid shaped blebs with either a clinopyroxene or olivine core and a thin plagioclase rim is commonly observed within this unit particularly for that close to intrusions of the ophitic gabbro. This texture is interpreted to have formed either by migration of material from the ophitic gabbro magma along a very fine 3d network or by pyroxene hornfels metamorphism related to intrusion of the ophitic gabbro.

6.4.3 Feldspathic clinopyroxenite

Crosscutting relationships suggest that the feldspathic clinopyroxenite is an older rock type that is potentially related to the meta-basalt (McBride, 2013). This rock

type is present either at the footwall/ophitic gabbro contact, meta- basalt/ophitic gabbro contact, or as amoeboid blebs within the ophitic gabbro (Figs. 6-3A, 6-3B, and 6-4C). The longitudinal section (Fig. 6-3A) shows that the feldspathic clinopyroxenite occurs as a large xenolith (~60 m thick and ~300 m long) within later ophitic gabbro intrusion, and also is stratigraphically underlain by a PGE mineralization zone which, as will be described later, is characterized by high PGE grades and low Cu/Pd. Thus, this rock type is an important stratigraphic marker above mineralization at this property. The mineralogy of the feldspathic clinopyroxenite, in decreasing order of abundances, comprises medium- to coarse-grained clinopyroxene (60-80 modal%), olivine (5-15 modal%), plagioclase (5-10 modal%), magnetite (less than 5 modal%), and trace disseminated sulfide minerals that are dominated by pyrrhotite and chalcopyrite. Both olivine and clinopyroxene are extensively fractured and replaced by secondary serpentine and chlorite (Fig. 6-5B). Plagioclase occurs either as coarse-grained subhedral phase interstitial to olivine and clinopyroxene cumulates, or as rounded fine-grained inclusions enclosed by clinopyroxene. Magnetite and sulfide minerals are typically within olivine and clinopyroxene as inclusions.

6.4.4 Layered Series

The Layered Series constitutes the main part of the Eastern Gabbro and is compositionally and texturally similar along the Eastern Gabbro (Good et al., 2015), this also applies to Area 41. It mainly consists of massive to modally layered olivine gabbro and weakly layered oxide augite melatroctolite, with a lesser amount of gabbroic anorthosite. The olivine gabbro and oxide augite melatroctolite are shown to be the same unit in Chapter 5. The Layered Series locally contains disseminated copper-sulfide mineralization, but the mineralization is typically related to albite-actinolite alteration and lacks PGE mineralization (Good et al., 2015; see Chapter 3). At Area 41, as elsewhere along the Eastern Gabbro, the Layered Series occurs stratigraphically above the Marathon Series (Figs. 6-3A and B).

6.4.4.1 Gabbroic anorthosite

The gabbroic anorthosite typically occurs as meter-sized xenoliths throughout the olivine gabbro at Area 41 and thus is older. However, this unit is believed to be genetically related to the Layered Series based on its similar inter-element ratios of incompatible elements with the Layered Series gabbro (Good et al., 2015). The gabbroic anorthosite has a very distinctive mottled appearance and consists of approximately 80 modal percent medium- grained, subhedral to anhedral plagioclase, very coarse- grained clinopyroxene (10 modal %) and olivine (5 modal %) oikocrysts, and 5 percent medium- to coarse- grained, interstitial to poikilitic magnetite.

6.4.4.2 Olivine gabbro

The olivine gabbro is medium to coarse grained (1-4mm) and shows massive to modal layering defined by a gradational increase in the abundance of plagioclase, or by alternating plagioclase-rich and clinopyroxene-rich layers (Fig. 6-4D). It consists of euhedral plagioclase (40-60 modal%), subhedral clinopyroxene (15-30 modal%), subhedral olivine (10-15 modal%), less than 10 modal% apatite and magnetite, less than 8 modal percent of subhedral alkaline feldspar, and less 5 modal% subhedral to anhedral biotite. Plagioclase locally occurs as chadocryst enclosed by olivine and clinopyroxene oikocrysts, and olivine is rimmed by clinopyroxene, indicating that the crystallization sequence is plagioclase, followed by olivine, then clinopyroxene. Apatite and magnetite normally are enclosed in, or interstitial to, olivine and plagioclase. Biotite occurs either as an interstitial phase, or as a poikilitic phase enclosing plagioclase, olivine, and clinopyroxene. Alkali feldspar in the olivine gabbro is perthite which partially encloses euhedral plagioclase grains (Fig. 6-5C).

6.4.4.3 Oxide augite melatroctolite

The oxide augite melatroctolite is texturally similar and gradational to the olivine gabbro at Area 41. It presents weak modal layering and is distinguished by a high abundance (10 to 20 modal %) of disseminated magnetite (Fig. 6-4D). The mineral

composition of this unit comprises, in approximately decreasing order of abundances, olivine (20-45 modal%), plagioclase (15-30 modal%), clinopyroxene (10-20 modal%), magnetite, and apatite (<10 modal%). Olivine and clinopyroxene are euhedral-subhedral, and occur between subhedral to anhedral plagioclase clusters. Magnetite and apatite are normally enclosed by, or less commonly interstitial to olivine and plagioclase.

6.4.5 Marathon Series

At surface at Area 41, the Marathon Series occurs as a band between the footwall and the Layered Series (Fig. 6-2). The Marathon Series is stratigraphically below the Layered Series (Figs. 6-3A and B). Ophitic gabbro is the dominant lithology of the Marathon Series, with lesser amounts of apatitic (olivine) clinopyroxenite and oxide melatroctolite. Based on the crosscutting relationships, e.g., the Marathon Series crosscuts both the meta-basalt and the Layered Series at Area 41, indicating the Marathon Series is the youngest series, although it stratigraphically is below the Layered Series (Fig. 6-3).

6.4.5.1 Ophitic gabbro

The ophitic gabbro resembles the Two Duck Lake gabbro at the Marathon deposit (Good et al., 2015), which is the main host to Cu-PGE mineralization at that deposit. It has a distinctive ophitic to subophitic texture (Fig. 6-4E), and consists of, in approximately decreasing order of abundance, subhedral plagioclase (40-70 modal%), subhedral clinopyroxene (15-30 modal%), euhedral to subhedral olivine (5-10 modal%), and less than 10 modal% magnetite and apatite. Based on textural relationships between various minerals (e.g., the overgrowth of olivine by clinopyroxene, the inclusion of apatite in the olivine, etc.), the crystallization sequence of this unit, from early to late, is plagioclase (apatite)-olivine-clinopyroxene-magnetite. Locally, the ophitic gabbro grades into the leucogabbro that contains a greater amount of plagioclase.

Based on variations in grain size, the ophitic gabbro can be subdivided into three subgroups: pegmatitic (>2 cm), coarse-grained (0.5-2cm), and medium-grained ophitic gabbro (<0.5 cm). The coarse-grained ophitic gabbro typically sits stratigraphically above the pegmatitic ophitic gabbro, and the latter is underlain by the medium-grained ophitic gabbro (Figs. 6-3A and B). Locally, the pegmatitic ophitic gabbro also occurs as pods within coarse-grained ophitic gabbro or as rims of Eastern Gabbro xenoliths. In contrast to coarse-grained and pegmatitic ophitic gabbro, olivine is rare in the medium-grained ophitic gabbro.

An important texture observed particularly in the pegmatitic ophitic gabbro is the replacement of earlier plagioclase by later plagioclase, and the later plagioclase is intergrown with chalcopyrite. EDS mapping (Fig. 6-6) and spot analyses show that the later plagioclase is more calcic than the earlier plagioclase. Similar textures were also observed by Good and Crocket (1994) and Shahabifar Far (2016) in the Two Duck Lake gabbro at the Marathon deposit, at the Four Dams in Chapter 3, and at the WD zone in Chapter 4. At Area 41, minerals in the ophitic gabbro are generally unaltered. However, there is some local development of secondary minerals such as chlorite, amphibole, serpentine, and calcite, particularly in the coarse-grained and pegmatitic ophitic gabbro (Fig. 6-5D). In addition, in pegmatitic ophitic gabbro, the magmatic apatite and biotite are locally replaced by the secondary apatite and biotite (Figs. 6-5E, 6-7, and 6-8), which are chlorine-rich relative to the primary phases (Figs. 6-7 and 6-8).

6.4.5.2 Apatitic (olivine) clinopyroxenite

The apatitic clinopyroxenite occurs as irregular-shaped pods stratigraphically below the ophitic gabbro, or is heterogeneously mixed with the ophitic gabbro (Figs. 6-3A, 6-3B, and 6-4F). Locally, it occurs as thin dikelets crosscutting the ophitic gabbro (Fig. 6-3A), indicating it perhaps is relatively younger than the ophitic gabbro. Outcrops of this unit are extremely rare as it is preferentially eroded. This unit hosts some PGE mineralization, but is less well mineralized than the ophitic gabbro. It

mainly consists of, in approximately decreasing order of abundance, medium- to coarse-grained subhedral clinopyroxene (30-60 modal%), olivine (10-20 modal%), euhedral apatite (5-15 modal%), plagioclase (5-10 modal%), and less than 10 modal% magnetite and biotite (Fig. 6-5F). Moderate to strong chlorite and actinolite alteration is commonly observed in this unit.

6.4.5.3 Oxide melatroctolite

The oxide melatroctolite pods typically are located within the main body of ophitic gabbro (particularly within the coarse-grained ophitic gabbro) (Figs. 6-3A and B). This unit contains a high abundance of subhedral magnetite (40-60 modal %), similar to the oxide augite melatroctolite in the Layered Series. This unit also contains olivine, clinopyroxene, plagioclase (the total amount of the three minerals generally is less than 30 modal %), and from 2 to 30 modal % euhedral apatite.

6.4.6 Breccia units

Three types of breccia units with different compositions of matrix and xenoliths were recognized. Type A consists of an ophitic gabbro matrix and angular xenoliths of meta-basalt rocks or footwall materials, which is similar to type A and B breccia units defined by Good et al. (2015) at the Marathon deposit. Type B is composed of an apatite clinopyroxenite-dominated matrix with meta-basalt or footwall xenoliths. Type C consists of meta-basalt rocks that were cut by multiple thin dikelets of the Marathon Series ophitic gabbro and/or apatitic clinopyroxenite, similar to type C breccia defined by Good et al. (2015) at the Marathon deposit. Note that these breccia rocks contain sulfide-bearing ophitic gabbro and apatitic clinopyroxenite, which are also important hosts to Cu-PGE mineralization at Area 41.

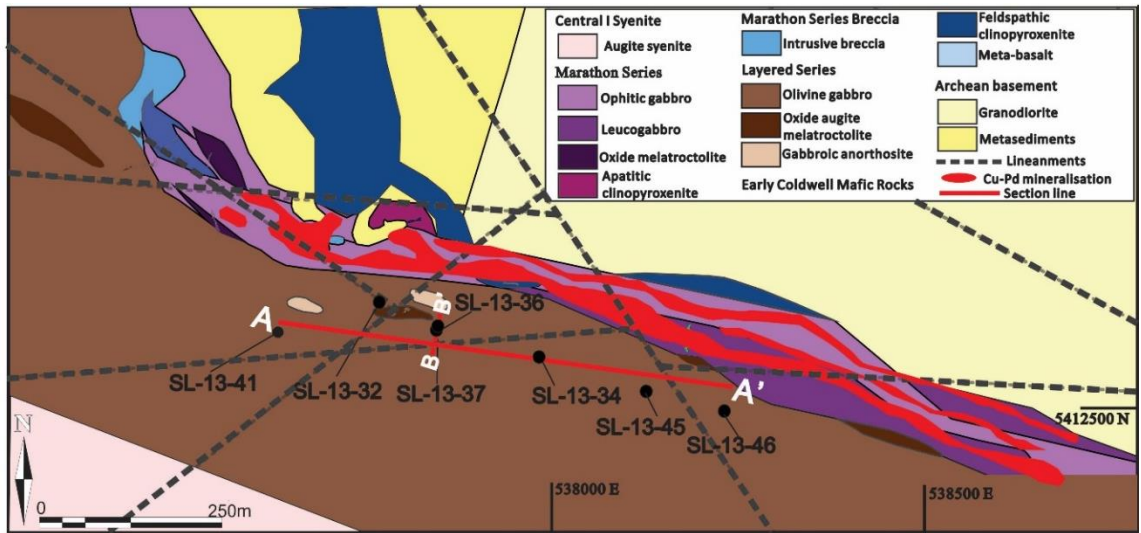

Figure 6-2. The surface geology at Area 41 (after McBride, 2013).

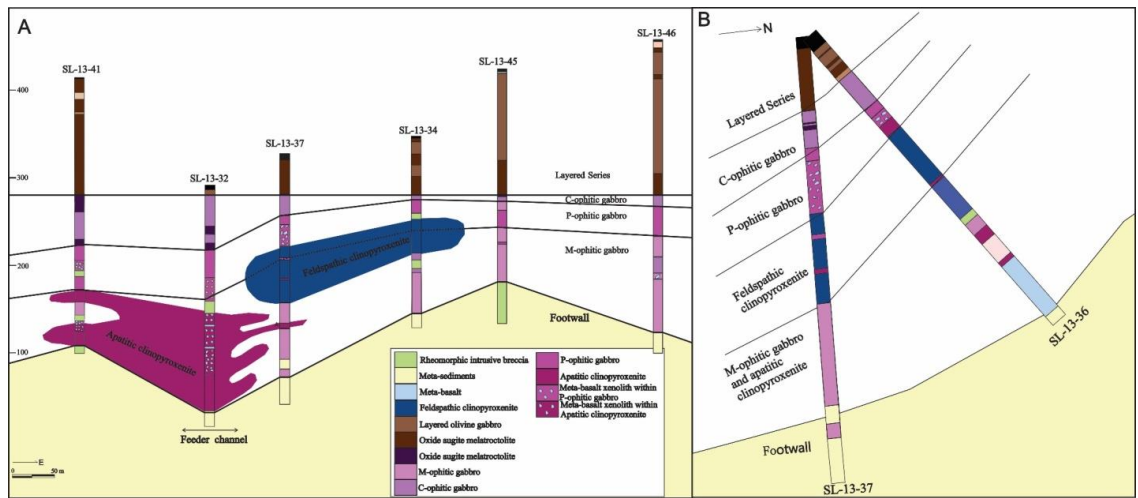

Figure 6-3. Stratigraphic relationships between different rock units. (A) A-A' longitudinal section as indicated in Figure 6-2 showing spatial distributions of different units; (B) B-B' cross section as indicated in Figure 6-2 showing geological boundaries of gabbro series. Prefix: P-pegmatitic, C-coarse-grained, M-medium-grained.

Figure 6-4. Field pictures of various rock units and textures. (A) Outcrop of rheomorphic intrusive breccia; (B) The meta-basalt is intruded by ophitic gabbro; (C) The feldspathic clinopyroxenite is crosscut by the ophitic gabbro; (D) The layering defined by the alternation of clinopyroxene and olivine- rich and plagioclase-rich sublayers of the layered series olivine gabbro, locally the olivine gabbro graded into the magnetite-rich oxide augite melatroctolite; (E) The typical ophitic texture of the ophitic gabbro; (F) The outcrop of apatitic clinopyroxenite, the non-weathered surface shows this unit is invariably mixed with the ophitic gabbro material.

Figure 6-5. Photomicrographs showing textures and alterations of different units. (A) Cross-polarized transmitted light photomicrograph showing the hornfels grade metamorphism of the meta-basalt unit, note the nearly 120° angles of boundaries between Pl crystals, the yellow mineral is the sericitic altered Pl; (B) Plane-polarized transmitted light photomicrograph showing the random Chl veinlets cutting Ol and Cpx in the feldspathic clinopyroxenite; (C) Cross-polarized transmitted light photomicrograph showing the poikilitic texture reflected by euhedral Pl chadocrysts enclosed by k-fsp oikocrysts, the sample is the olivine gabbro; (E) Cross-polarized transmitted light photomicrograph showing the Chl aggregates in the pegmatitic ophitic gabbro (D) Cross-polarized transmitted light photomicrograph showing the secondary Ap rims the primary magmatic Ap in the pegmatitic ophitic gabbro; (F) Plane-polarized transmitted light photomicrograph showing euhedral Ap cumulates with interstitial Pl in the apatitic clinopyroxenite. Abbreviations: Amph=amphibole, Ap=apatite, Bt=biotite, Ccp=chalcopyrite, Chl=chlorite, Cpx=clinopyroxene, K-fsp=K feldspar, Mt=magnetite, Ol=olivine, Pl=plagioclase.

Figure 6-6. Textures showing earlier plagioclase was replaced by later more calcic plagioclase that occurs intergrown with chalcopyrite (and pentlandite). Note that there is some carbonate alteration on the plagioclase (see the white mineral on Ca mapping).

Figure 6-7. Wavelength dispersive spectroscopy (WDS) Cl and F mapping showing secondary apatite replaces the magmatic apatite in pegmatitic ophitic gabbro, the magmatic apatite is rich in F, whereas the secondary apatite is rich in chlorine.

Figure 6-8. WDS Cl, Ba, and K mapping showing secondary biotite replaces the magmatic biotite in pegmatitic ophitic gabbro, the magmatic biotite is rich in Ba and K, whereas the secondary biotite is rich in chlorine.

All three series' units at Area 41 share similar petrographic characteristics with the same series' units at the Marathon deposit as described by Good et al. (2015), and also similar to those at Four Dams as described in Chapter 3. Note that Four Dams area is about 15 km south of Area 41.

6.5 Geochemical Characteristics of the Layered and Marathon Series at Area 41

Results of Good et al. (2015) and the work in Chapter 3 show that the units of the Eastern Gabbro assemblage at the Marathon deposit and Four Dams are geochemically distinctive. Adopting this concept, the classification of units recognized by drill core logging and petrography at Area 41 is evaluated using lithogeochemistry in order to establish the reliable stratigraphy and investigate its relationship with PGE mineralization. This is particularly important when considering that some rock units in the Eastern Gabbro assemblage are hosts to

significant Cu-Pd mineralization but are petrographically similar to other barren gabbroic units. For example, as will be shown in section 6.6.1, at Area 41 the Marathon Series hosts all known PGE mineralization whereas the Layered Series and meta-basalt lack PGE mineralization, therefore successfully recognizing these series' units is key to mineral exploration. The meta-basalt makes up a small portion of the Eastern Gabbro and shows unique pyroxene hornfels metamorphic texture, and thus is easily identified. The Layered Series constitutes the bulk of the Eastern Gabbro and is petrographically similar to the Marathon Series units. An important objective of this study is to create a tool for exploration at Area 41 through geochemical discrimination of the Marathon Series gabbro from the Layered Series gabbro.

6.5.1 Discrimination using lab-based results

Rock units are characterized by the primitive mantle-normalized abundances of Ce, Y, Nb, and Zr. The purpose for normalizing these elements is to keep consistent with the results from Good et al. (2015) for the units at the Marathon deposit, thus facilitating the comparison. These trace elements are chosen because: 1) they are all incompatible elements in mafic rocks, and as such, their ratios, can serve as indices to degrees of either partial melting and/or crustal contamination; and, 2) cerium and Y are the most and second most abundant REE in the data set and so will minimize the impact of analytical uncertainty in the interpretation. The average normalized Ce/Y and Nb/Zr values for various gabbro units are summarized in Table 6-7.

The meta-basalt, Layered Series, and Marathon Series are geochemically different. For example, the average normalized Ce/Y and Nb/Zr for the feldspathic clinopyroxenite are 3.95 ($1\sigma=0.77$) and 2.42 ($1\sigma=0.42$), lower than those for the olivine gabbro (average Ce/Y=14.23 ($1\sigma=0.77$), average Nb/Zr=6.79 ($1\sigma=0.55$)), and the Marathon Series ophitic gabbro (average normalized Ce/Y=11.91 ($1\sigma=2.53$), average Nb/Zr=5.69 ($1\sigma=0.85$)). These values are broadly similar to those determined by Good et al. (2015) for the same series' units at the Marathon deposit

except for the ophitic gabbro. At the Marathon deposit, the average normalized Ce/Y and Nb/Zr for the Two Duck Lake gabbro are 6.58 ($1\sigma=1.0$) and 3.63 ($1\sigma=1.13$), lower than those determined in the current work. Primitive mantle-normalized Ce vs. Y and Nb vs. Zr diagrams (Figs. 6-9 and 6-10) are created to better illustrate differences for different series units. Excluding the apatitic clinopyroxenite, which shows somewhat randomly distributed data points possibly because of the influence of apatite cumulates, the feldspathic clinopyroxenite, the Layered Series, and the Marathon Series are divided almost into three fields as separated by ratio lines of 6.2 and 15. Therefore, it seems that primitive mantle-normalized Ce/Y and Nb/Zr are useful to distinguish the Marathon Series rocks from the Layered Series and the meta-basalt at the Eastern Gabbro. Differences in Ce/Y and Nb/Zr for these igneous series are not likely to have resulted by fractional crystallization of a single batch of magma (they are incompatible), but rather reflect their different magma sources or degrees of contamination.

Table 6-7. Summary of primitive Mantle-Normalized Ce/Y and Nb/Zr for various gabbro units within the Eastern Gabbro at Area 41. Notes: Primitive mantle values for Ce, Y, Zr, and Nb of 1.675, 4.3, 10.5, and 0.658 ppm, respectively from McDonough and Sun (1995).

Series	Unit	No. of samples	Normalized Ce/Y			Normalized Nb/Zr		
			Avg	SD	Range	Avg	SD	Range
Meta basalt	Feldspathic clinopyroxenite	6	3.9	0.77	12.7-13.8	2.4	0.42	2.1-3.2
Layered	Olivine gabbro	11	14.2	0.68	13.4-15.5	6.8	0.55	6.1-7.8
	Oxide augite melatroctolite	12	13.9	0.64	13.1-14.8	7.8	1.21	6.3-10.2
	Ophitic gabbro	13	11.9	2.33	7.0-14.4	5.7	0.85	4.5-7.6
Marathon	Apatitic clinopyroxenite	7	6.1	2.68	4.0-10.0	2.4	1.23	1.4-8.0
	Oxide melatroctolite	7	13.4	0.41	12.7-13.8	6.3	0.86	5.1-7.1
	Coubran basalt*	18	8.9	3.63	5.0-17.7	3.5	0.33	2.8-4.2

*Data are from Cundari (2012).

The work in Chapter 3 successfully applied Ba and V/Ti to distinguish the Marathon Series units from the Layered Series units at Four Dams area. These two parameters are adopted here to differentiate igneous series at Area 41. Lab-based Ba and V/Ti are used here, but it is also possible to use pXRF Ba and V/Ti because all these elements can be acquired by pXRF (see Chapters 3 and 4). Figure 6-11 shows that

the Layered Series gabbro contains Ba contents (*ca.* 1000- *ca.* 6000 ppm) significantly higher than the Marathon Series rocks (<1000 ppm) and the feldspathic clinopyroxenite (<100 ppm). By contrast, V/Ti ratios for the Layered Series units (below *ca.* 0.02) are lower than those for the Marathon Series units (*ca.* 0.02- *ca.* 0.07) and the feldspathic clinopyroxenite (*ca.* 0.02- *ca.* 0.05). Therefore, in addition to Ce/Y and Nb/Zr, whole-rock Ba and V/Ti are also useful parameters to distinguish the Marathon Series from other igneous series.

Figure 6-9. Comparison of primitive mantle-normalized Ce vs. Y for various units of the Eastern Gabbro at Area 41. Primitive values for Ce (1.675 ppm) and Y (4.3 ppm) are from McDonough and Sun (1995). PM=primitive mantle.

Figure 6-10. Comparison of primitive mantle-normalized Nb vs. Zr for various units of the Eastern Gabbro at Area 41. Primitive values for Nb (0.658 ppm) and Zr (10.5 ppm) are from McDonough and Sun (1995). PM=primitive mantle.

Figure 6-11. Whole-rock Ba vs. V/Ti for various rocks of the Eastern Gabbro at Area 41.

6.5.2 Discrimination using field portable instruments-based results

The evaluation of results from field portable techniques to distinguish the units is significant because: 1) the results can be acquired directly in the field without any time delay, thus improving the decision-making process; and, 2) it allows the acquisition of a large data set at a relatively low cost, thus can be used to create the high dense chemostratigraphy, which can then be compared to the stratigraphy from core logging. pXRF Al_2O_3 , CaO , Fe_2O_3 , P_2O_5 , K_2O , Ba, Sr, Zr, and bSEM-EDS Mg#s of olivine and clinopyroxene are used in this section to distinguish different series units at Area 41 and establish the geochemical stratigraphy. Data accuracy and precision acquired from both portable techniques have been established in Chapters 3 and 4.

6.5.2.1 Down-hole profiles

In Chapter 3, we found that the Layered Series and the Marathon Series at Four Dams can be distinguished by investigating down-hole variations in whole-rock Zr and Mg#s of olivine and clinopyroxene, i.e., the Layered Series presents smooth trends in these parameters whereas the Marathon Series does not. Note that all these parameters are useful proxies to denote magma differentiation trends. In this section, we investigate whether this method still works at Area 41. Geochemical profiles of bSEM-EDS Mg#s of olivine and clinopyroxene, and pXRF whole-rock Zr down two representative drill holes (SL-13-37 and SL-13-32) are displayed in Figures 6-12 and 6-13.

Two significant observations from the down-hole profiles are made. First, the Mg#s of olivine and clinopyroxene of the Layered Series increase down hole, and whole-rock Zr contents of the Layered Series decrease down hole, which is a normal evolution trend. The Marathon Series units including the ophitic gabbro and apatitic clinopyroxenite, by contrast, have erratic variations in these parameters over short distances. The feldspathic clinopyroxenite also displays an overall normal evolution trend, but it appears to be more primitive than the Layered Series and the Marathon

Series. Second, the Mg#s of olivine and clinopyroxene for coarse-grained and pegmatitic ophitic gabbro samples have 1σ standard deviation= ~ 1 - ~ 3 (Table 6-5), which are more variable than the medium-grained ophitic gabbro (SD= ~ 1 - ~ 1.8 , Table 6-5), the Layered Series (SD= ~ 0.5 - ~ 1 , Table 6-5), and the feldspathic clinopyroxenite (SD= ~ 0.4 - ~ 1.3 Table 6-5). These differences are highlighted in Figures 6-12 and 6-13 (see error bars in both figures).

Figure 6-12. Down-hole variations in Mg# of olivine, Mg# of clinopyroxene, and whole-rock Zr for drill hole SL-13-37. Two ends of the error bar represent the minimum and maximum of the mineral chemical data, see text for full explanations. Note that the Cu/Pd ratios are in log-scale and ratios > 20000 are not shown. LS: The Layered Series, MS: The Marathon Series. Lithology legend is same as Figure 6-3.

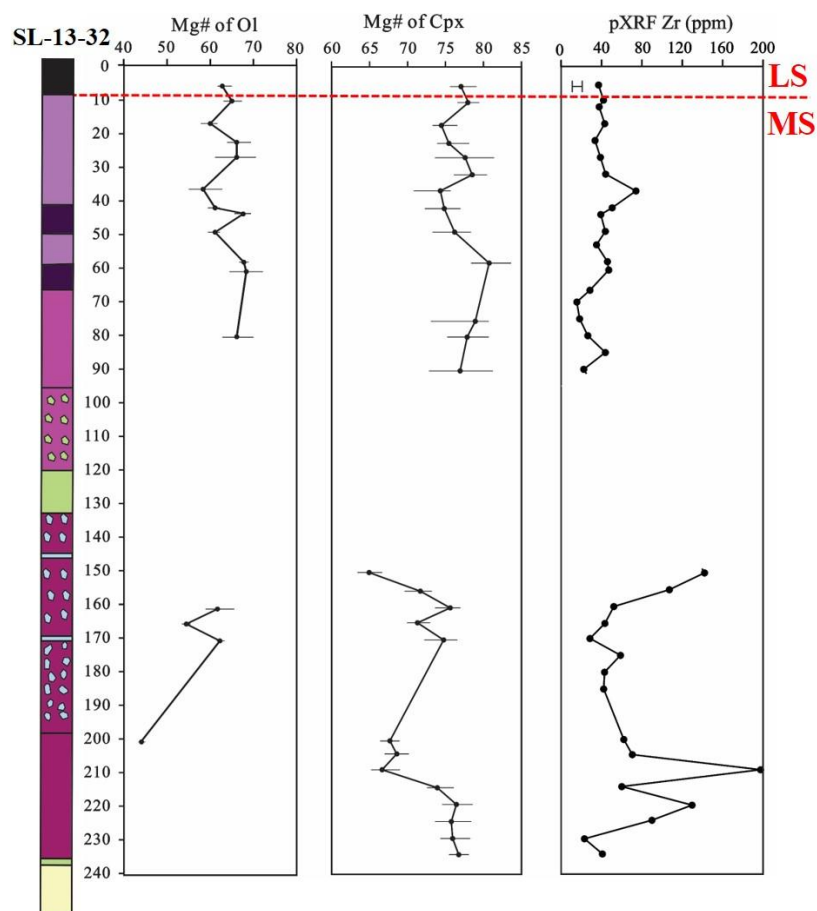

Figure 6-13. Down-hole variations in Mg# of olivine, Mg# of clinopyroxene, and Zr contents for drill hole SL-13-32. LS: The Layered Series, MS: The Marathon Series. Lithology legend is the same as Figure 6-3.

6.5.2.2 Chemical stratigraphy

In order to establish the reliable stratigraphy, particularly when the drill cores were logged by several people, a geochemical stratigraphy created based on pXRF and bSEM-EDS analyses are compared to the stratigraphy. Down-hole mapping of pXRF whole-rock Al_2O_3 , CaO , Fe_2O_3 , P_2O_5 , K_2O , Sr , and Ba , and bSEM-EDS Mg#s of olivine and clinopyroxene are correlated with the igneous stratigraphy in Figure 6-14. The chemostratigraphy is basically consistent with the stratigraphy. For instance, it shows that the Layered Series generally contains higher K_2O , Ba , and Sr contents than the Marathon Series. The medium-grained ophitic gabbro contains lower P_2O_5 , Fe_2O_3 , higher Al_2O_3 and Sr contents than the coarse-grained and pegmatitic ophitic gabbro. The feldspathic clinopyroxenite and the apatitic

clinopyroxenite are also clearly indicated in the geochemical stratigraphy by their low Al_2O_3 , P_2O_5 , K_2O , Ba, Sr abundances for the feldspathic clinopyroxenite, the high Mg#s of olivine and clinopyroxene for the feldspathic clinopyroxenite, and high CaO and P_2O_5 abundances for the apatitic clinopyroxenite.

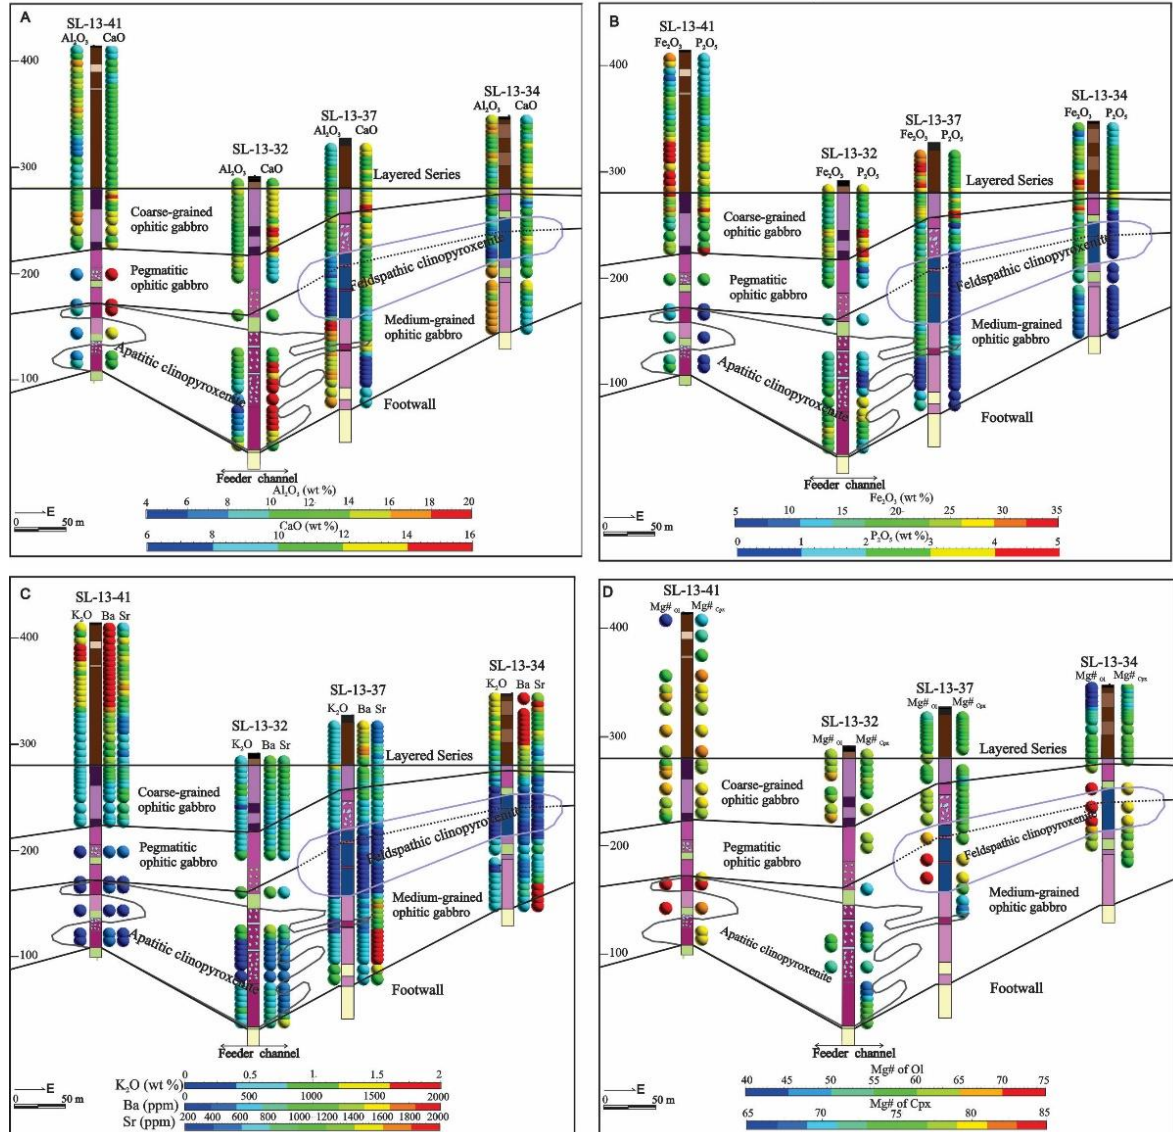

Figure 6-14. Chemical stratigraphy created based on pXRF and bSEM-EDS analyses. Legends for lithology as in Figure 6-3.

6.6 Characterization of mineralization

6.6.1 The relationship between mineralization and stratigraphy

The distribution of Cu-PGE mineralization at surface is shown in Figure 6-2. The mineralization is mainly hosted by, and has a similar strike with, the ophitic gabbro

of the Marathon Series. To further examine the relationship between the mineralization and stratigraphy and determine the types of mineralization, down-hole variations in Cu/Pd (calculated using exploration assay provided by Stillwater Canada Inc.) relative to igneous stratigraphy are shown in Figure 6-15 because, this ratio can be used to evaluate whether the mineralization is PGE rich or Cu rich. In addition, boundaries of mineralization that were defined by Stillwater Canada Inc. were added in this figure.

Generally, three types of mineralization characterized by different Cu/Pd are recognized. Type 1 mineralization is Cu-rich and PGE-poor, with Cu/Pd >16000. It is mainly hosted by the coarse-grained ophitic gabbro, with lesser amounts hosted by the medium-grained ophitic gabbro. Type 2 is PGE mineralization with Cu/Pd varying from 2000 to 10000. It is mainly hosted by the apatitic clinopyroxenite, with lesser amounts hosted by the pegmatitic ophitic gabbro. Type 3 mineralization is characterized by high PGE grades and low Cu contents, with Cu/Pd <2000. This mineralization type is predominantly hosted by the pegmatitic ophitic gabbro.

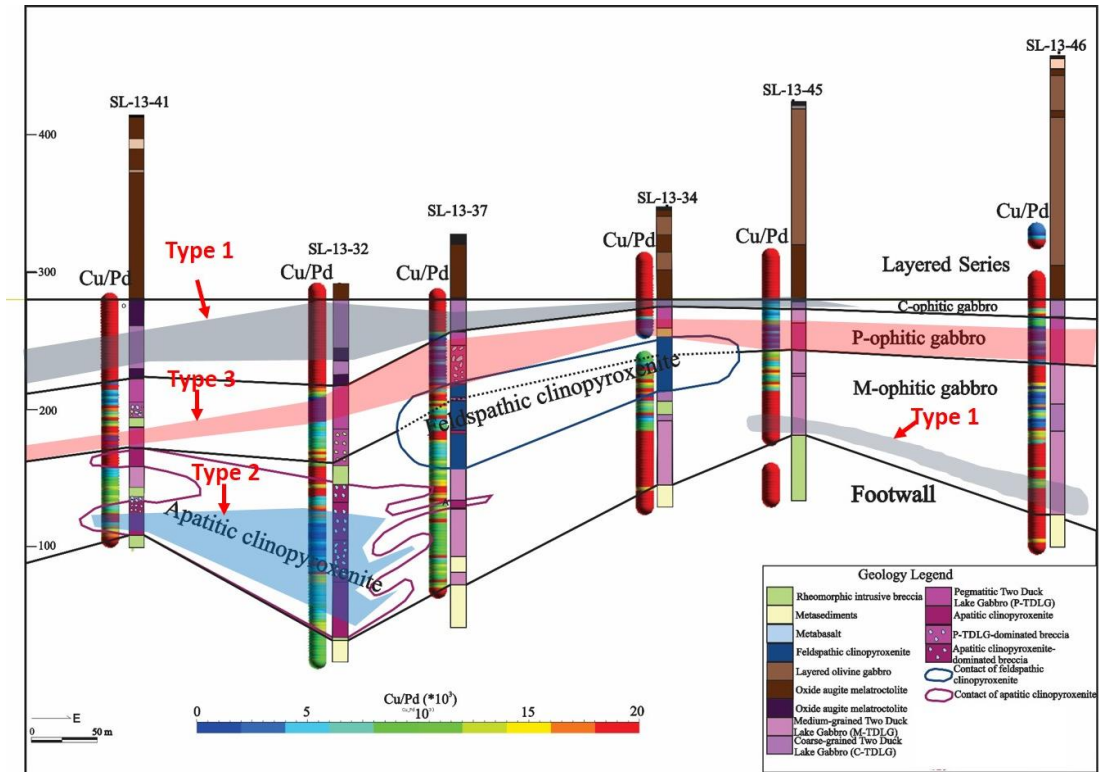

Figure 6-15. Longitudinal section showing stratigraphic distributions of Cu/Pd and different types of mineralization. The column represents drill holes, and bubbles at both sides of the column represent geochemical values. Different types of sulfide mineralization (see text for full details) are outlined using coloured transparent shaded columns. Prefix: P-pegmatitic, C-coarse-grained, M-medium-grained.

6.6.2 Sulfide minerals and textures

In this section, sulfide minerals within the pegmatitic, coarse-grained, and medium-grained ophitic gabbro, as well as those within the apatitic clinopyroxenite are described with emphasis on their mineralogy and textures. The bulk of sulfide mineralization in these units is disseminated that generally comprises less than 5 modal percent of the rock and are dominantly interstitial to the silicate minerals. However, sulfide mineralogy appears to be different in these units, particularly the relative proportions of pyrrhotite and chalcopyrite.

6.6.2.1 Medium-grained ophitic gabbro

In medium-grained ophitic gabbro, sulfide minerals generally consist of pyrrhotite, chalcopyrite, with minor amounts of cubanite and pentlandite. The relative proportion of pyrrhotite is higher than that of the chalcopyrite, and in rare cases the

pyrrhotite appears to be the dominant sulfide phase (Fig. 6-16A). In addition, chalcopyrite normally replaces pyrrhotite, and both are very rarely associated with hydrous silicate minerals (Fig. 6-17A). Samson et al. (2008) also observed the replacement of pyrrhotite by chalcopyrite in mineralized samples at the Marathon deposit.

6.6.2.2 Coarse-grained ophitic gabbro

The coarse-grained ophitic gabbro also contains pyrrhotite and chalcopyrite as the main sulfide minerals. However, compared to the medium-grained ophitic gabbro, it has a higher relative proportion of chalcopyrite (Fig. 6-16B). In addition, minor pentlandite is rimed by chalcopyrite (Fig. 6-17B). Sulfide minerals in this unit normally are interstitial to silicate minerals, locally the chalcopyrite and pyrrhotite are closely related to secondary magnetite aggregates (Fig. 6-17C). The secondary magnetite is free of ilmenite exsolution and does not show a visible Ti peak in the X-ray spectrum when analyzed by bSEM-EDS.

6.6.2.3 Pegmatitic ophitic gabbro

The modal percent of sulfide minerals in the pegmatitic ophitic gabbro varies significantly from 10% (Fig. 6-16C) to less than 0.5% (Fig. 6-16D). Sulfide minerals consist predominantly of chalcopyrite and pyrrhotite, with minor amounts of pentlandite, cubanite, galena, pyrite, and trace bornite. The relative proportion of chalcopyrite in this unit is higher than that in the coarse-grained ophitic gabbro. This is particularly true for the pegmatitic ophitic gabbro with trace sulfide minerals (<0.5 modal %) where the relative proportion of chalcopyrite can increase up to nearly 100% (Fig. 6-16D). Sulfide minerals normally occur either interstitial to primary silicate minerals, or show close associations with secondary minerals such as amphibole, chlorite, and secondary magnetite (Fig. 6-19D). Some chalcopyrite is intergrown with plagioclase (Figs. 6-17E and F), which replaces the earlier less calcic plagioclase (Fig. 6-6). In the case when the pegmatitic ophitic gabbro contains trace sulfide minerals, chalcopyrite grains occur interstitial to primary olivine grains (Figs. 6-17G and H). It is noteworthy that these chalcopyrite grains commonly

enclose, or show close spatial relations, to PGM minerals, and locally are rimmed by pyrrhotite, pentlandite, secondary magnetite, and/or partially are overlapped by chlorite (Fig. 6-17H).

6.6.2.4 Apatitic clinopyroxenite

Sulfide mineral assemblage and relative proportions of chalcopyrite and pyrrhotite in the apatitic clinopyroxenite are generally similar to those in the pegmatitic ophitic gabbro (Fig. 6-16E). However, a higher amount of pyrite is observed in this unit. Pyrite grains are euhedral to subhedral, and locally occur as aggregates within calcite that are surrounded by chalcopyrite and pyrrhotite (Fig. 6-17I). Some pyrrhotite grains host many sphalerite inclusions and are replaced by chalcopyrite at their rims (Fig. 6-17J). Figures 6-17K and L show that locally sulfide minerals in this unit are rimmed by secondary magnetite, which are all enclosed by hydrothermal chlorite.

Figure 6-16. Polished thin section scans and corrected photos with sulfide mineralization highlighted and silicate phases plus magnetite ignored. (A) SL-13-36-152.8, medium-grained ophitic gabbro, Po is the dominant sulfide mineral; (B) SL-13-27-80.4, coarse grained ophitic gabbro which shows an elevated proportion of Ccp that occurs intergrown with Po; (C) SL-13-37-65.7, pegmatitic ophitic gabbro with a high proportion (>10 modal %) of sulfide mineralization, note that Ccp replaces Po; (D) SL-13-36-62, pegmatitic ophitic gabbro with trace sulfide mineralization (<0.5 modal %), Ccp is the only visible sulfide mineral; (E) SL-13-32-214.5, disseminated sulfide mineralization including Ccp and Po in apatitic clinopyroxenite. Abbreviations: Ccp=chalcopyrite, Po=pyrrhotite.

Figure 6-17. Reflected light photomicrography showing the assemblage and textures of sulfide minerals. (A) SL-13-36-156.8 medium-grained ophitic gabbro, Ccp replaces Po, both are interstitial to plagioclase, olivine, and clinopyroxene; (B) SL-13-32-37 coarse-grained ophitic gabbro, Pn is replaced by Ccp at the rim; (C) SL-13-27-80.4 coarse-grained ophitic gabbro, tiny grained Ccp and Po occur rimmed or surrounded by secondary Mt; (D) SL-13-37-70 pegmatitic ophitic gabbro, Ccp grains are replaced by secondary Mt, all are surrounded by chlorite clusters; (E)-(F) SL-13-32-165.5 pegmatitic ophitic gabbro, Ccp and Pn (and Po) occur intergrown with Pl; (G)-(H) SL-13-37-80.05 pegmatitic TDLG, the separate Ccp grain interstitial to olivine aggregates, the Ccp is rimmed by secondary Mt and hosts some PGM grains; (I) SL-13-32-204.5 apatitic clinopyroxenite, Py aggregates surrounded by Ccp and Po; (J) SL-13-36-76 apatitic clinopyroxenite, Po contains many Sp inclusions and have Ccp rims; (K) SL-13-34-75 apatitic olivine clinopyroxenite, Pn and Ccp are surrounded by hydrothermal minerals, note the Ccp is partially replaced by secondary Mt and there is a PGM grain related to the Ccp; (L) SL-13-34-75 apatitic clinopyroxenite, Ccp and Pn are replaced by secondary Mt, all are enclosed by hydrothermal Chl. Abbreviations: Cal-calcite,

Ccp=chalcopyrite, Chl=chlorite, Mt=magnetite, Pn=pentlandite, Po=pyrrhotite, Py=pyrite, Sp=sphalerite.

6.6.3 *Platinum-group minerals (PGM) mineralogy*

A detailed characterization of PGM and gold minerals for Area 41 occurrence was conducted by Cabri (2014). In that study, samples were screened, split, assayed size by size, and followed by high-grade heavy mineral concentrates using hydroseparation. Mineral separates (238 grains) were then mounted on monolayer polished sections (6 polished sections) and analyzed by SEM-EDS. Cabri (2014) concluded that the PGM mineralogical compositions vary significantly, but can be basically subdivided into two groups: Pd-PGM and Pt-PGM. By mass%, the plumbian PGM (e.g., zvyagintsevite) and sperrylite are the dominant Pd-PGM and Pt-PGM, respectively.

In this study, we conducted a separate characterization of PGM mineralogy using bSEM-EDS. Instead of using mineral separates, thin sections and thin section blocks were scanned by bSEM for the search of potential PGM minerals, their compositions are then analyzed by the equipped EDS analyzer. Compared to the method of Cabri (2014), sample preparation in this study is simpler and less time consuming. The proportions of PGM are less quantitative but PGM-related textures such as their hosts and relations to surrounding silicates can be used to establish the paragenesis of PGE mineralization, thus the results are complementary to those of Cabri (2014).

A total of 81 PGM grains were found (Table 6-8, Fig. 6-18). Of them, 68.75% (55 grains) are Pd-PGM, 21.25% (17 grains) are Pt-PGM, 10% (8 grains) are electrum and telluride minerals including Au-Ag and Ag-Te alloys. Sperrylite is the dominant Pt-PGM, similar to results of Cabri (2014). In addition, the most common Pd-PGM is kotulskite which is also the most frequent Pd-PGM found by Cabri (2014). Thus, results of the current work are comparable to those of Cabri (2014), and the bSEM-EDS is capable of providing reliable results on PGM characterization.

Representative thin sections with PGE grades, Cu/Pd ratios, degrees of alteration, and PGM assemblages are tabulated in Table 6-9. Backscattered images of representative PGM minerals are displayed in Figure 6-19. Kotulskite is the most common PGM and is present in both fresh and extensively altered samples. Skaergaardite, tetraferroplatinum, plumbopalladinite grains were commonly observed in fresh samples. By contrast, As-, Sb-, and Te-bearing PGM such as sperrylite, arsenopalladinite, menshikovite, hollingworthite, mertierite-II, stillwaterite, and telluride were only found in samples with minor, moderate and extensive alteration. Backscattered images show that the kotulskite occurs typically as inclusions or at margins of base metal sulfide minerals such as chalcopyrite, pyrrhotite, pyrite, and pentlandite (Figs. 6-19A and B). Rarely, kotulskite is intergrown with stillwaterite and mertierite-II that form the PGM aggregates (Figs. 6-19C and D). Skaergaardite, isoferroplatinum, and tetraferroplatinum are typically occur within or at the margins of chalcopyrite grains (Figs. 6-19E-H). Some PGM grains, particularly As-bearing PGM are enclosed by secondary minerals such as chlorite, amphibole, and actinolite (Figs. 6-19I-K). However, magmatic sulfide grains are also observed in the very proximity of these PGM grains. Telluride minerals and electrum are observed within chalcopyrite grains (Fig. 6-19L).

Table 6-8. Mineralogy of Platinum Group Minerals

PGM	Formula	No.	Description
Sperrylite	PtAs ₂	13	Commonly hosted by secondary minerals in the vicinity of sulfides, some occur at the contact of Pl grains or intergrown with Ccp
Tetraferroplatinum	PtFe	3	Commonly occur intergrown with Ccp, or as inclusions in Ccp
Isoferroplatinum	(Pt, Pd) ₃ Fe	1	Intergrown with Ccp
Kotulskite	Pd(Te,Bi)	34	Mostly occur as inclusions or at margins of Ccp, Po, and Pn, rarely is enclosed by Py, Hbl, and Pl
Arsenopalladinite	Pd ₈ (As, Sb, Te, Bi) ₃	6	Mostly show close relations to secondary minerals such as Act and Amph, rarely within Pl and Ccp.
Menshikovite	Pd ₃ As ₃ Ni ₂	5	Commonly at the contact between Ccp and Pl, or secondary minerals

Hollingworthite	(Rh, Pt, Pd)AsS	3	Commonly at the contact between sulfides and biotite (secondary?), or within allanite.
Mertierite-II	Pd ₈ (Sb) ₃	3	Intergrown with kotulskite
Sobolevskite	PdBi	2	Hosted by Ccp
Stillwaterite	Pd ₈ As ₃	1	Intergrown with kotulskite
Plumbopalladinite	Pd ₃ Pb ₂	1	Within Pl
Skaergaardite	PdCu	1	Intergrown with Ccp
Telluride	Ag ₂ Te	3	Within Pl and Ccp
Electrum	Au-Ag	5	Intergrown with Ccp

6.6.4 Inter-element relationships

Developing an understanding of the inter-relationships for Cu, Pd, Pt, Ir, Rh, S, and Se is key to unravel the dominant processes responsible for sulfide deposition at Area 41. Cu, S, Pd, and Pt used in this section mostly are Stillwater Inc. exploration assays, Rh, Ir, Se and additional Cu and S results are from analyses on a small subset of PGE well mineralized pegmatitic ophitic gabbro samples. Note that only Marathon Series samples that contain >0.01 ppm Pd and Pt are considered in this section. Most coarse-grained ophitic gabbro is PGE-poor ($\text{Cu/Pd} > 10000$ and <0.01 ppm Pt+Pd) with PGE grades orders of magnitude lower than other rock types, thus this filter only allows a small subset of this unit to be included.

Whole-rock Cu/S is largely dependent on proportions of chalcopyrite, pyrrhotite, and bornite, thus it can be used to predict proportions of sulfide minerals. Figure 6-20A shows that all samples fall along a positive trend within the field between 100% chalcopyrite and 95% pyrrhotite. Specifically, the medium-grained ophitic gabbro contains a higher abundance of sulfur than other units and plots close to the 5% chalcopyrite-95% pyrrhotite line, indicating that the dominant sulfide mineral of this unit is pyrrhotite. Compared to the medium-grained ophitic gabbro, the coarse-grained ophitic gabbro has a slightly higher proportion of chalcopyrite. The pegmatitic ophitic gabbro and the apatitic clinopyroxenite samples plot close to the 50% chalcopyrite-50% pyrrhotite line, some of pegmatitic ophitic gabbro samples even almost fall along the 100% chalcopyrite line. These suggest that the pegmatitic ophitic gabbro and apatitic clinopyroxenite contain higher proportions of chalcopyrite than the medium-grained and the coarse-grained ophitic gabbro. All these observations agree with petrographic descriptions in section 6.6.2.

Three important observations on Pd vs. S and Pt vs. S diagrams (Figs. 6-20B and C) are: 1) there is a positive relationship between Pd (and Pt) and S for the medium-grained ophitic gabbro, but not for the other units; 2) several pegmatitic ophitic gabbro samples are very enriched in Pd and Pt ($\text{Pd} > 3000$ ppb, $\text{Pt} > 1000$ ppb Pt, type

3 mineralization), but contain trace amounts of sulfide minerals as reflected by their low S contents (<0.1 wt.%); and, 3) the similarity between Pd vs. S and Pt vs. S diagrams indicate the coherent behaviour of Pd and Pt, Pd/Pt ratios for all rock units are within 1-4 (Fig. 6-20D). However, Figure 6-20E displays a general increasing Pd/Pt with increasing Pt trend and so the behavior is nonlinear and can best be fit by a power expression.

Figure 6-20F shows that the medium-grained ophitic gabbro generally falls along the line of $\text{Cu/Pd} = 10000$. By contrast, the coarse-grained and pegmatitic ophitic gabbro, as well as the apatitic clinopyroxenite show poor correlations between Cu and Pd. Cu/Pd values for the apatitic clinopyroxenite are generally within 1000-10000 (the mantle range), whereas those for the pegmatitic ophitic gabbro vary significantly from <500 to >10000 .

Figures 6-20G-I show that there are good correlations between Pd and Ir, Pd and Rh, and Ir and Rh for selected PGE-enriched pegmatitic ophitic gabbro samples. In addition, this suite of samples has S/Se ratios vary between 800 and 2000 with an average of *ca.* 1200 (Fig. 6-20J), which are below the mantle range and similar to S/Se of the PGE mineralized samples at W-horizon of the Marathon deposit as measured by Ruthart (2013). Figures 6-20 K and L show that this suite of pegmatitic ophitic gabbro samples has a negative relationship between PGE (Pd+Pt) grade and S/Se, and has a poor relationship between Pd/Ir and S/Se, with Pd/Ir nearly constant at around 400. Figure 6-21 shows that S/Se ratios for this suite of samples present a zig-zag down-hole variations, which is in a roughly opposite sense with the down-hole profile of Pt+Pd. Both are significant different with the profile of the degree of alteration which seems generally increase with depth (Fig. 6-21).

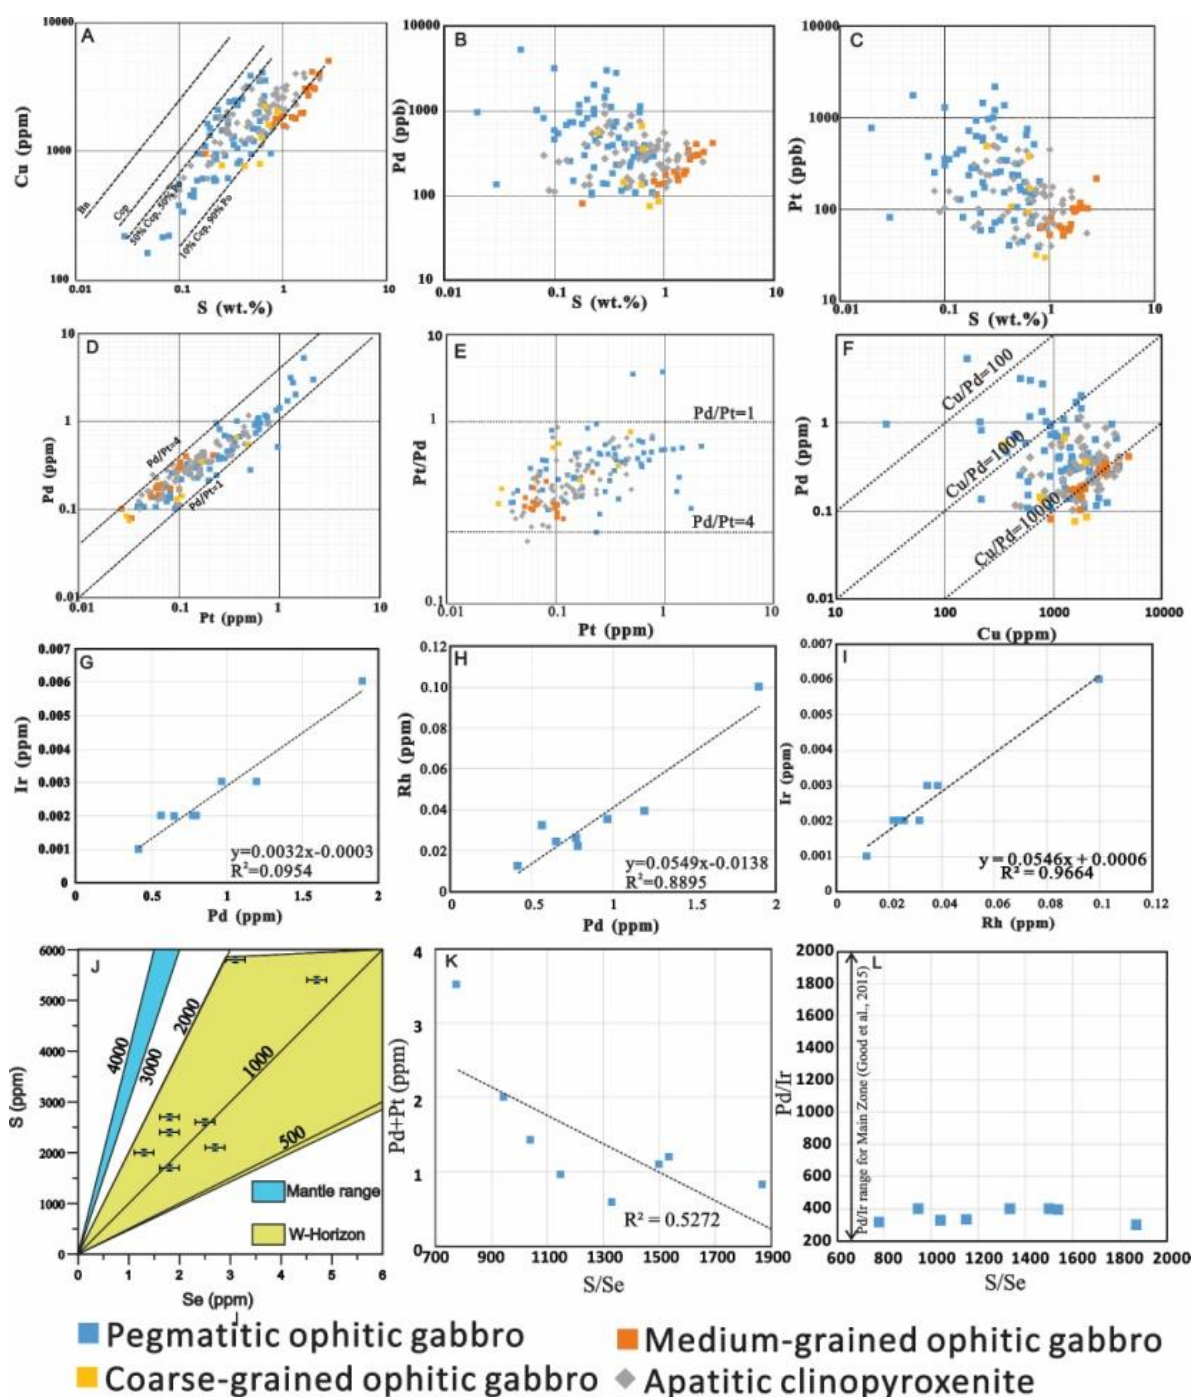

Figure 6-20. Inter-element relationships between PGE elements, S, and Se for sulfide mineralized samples at Area 41. (A) Cu vs. S, dashed lines indicate different proportions of chalcopyrite and pyrrhotite; (B) Pd vs. S; (C) Pt vs. S; (D) Pd vs. Pt; (E) Pt/Pd vs. Pt; (F) Pd vs. Cu, dashed lines indicate different Cu/Pd ratios; (G) Pd vs. Ir; (H) Pd vs. Rh; (I) Rh vs. Ir; (J) S vs. Se, the error bar represents 2 σ analytical precision determined by multiple analyses on the same sample; (K) (Pd+Pt) vs. S/Se; (L) Pd/Ir vs. S/Se.

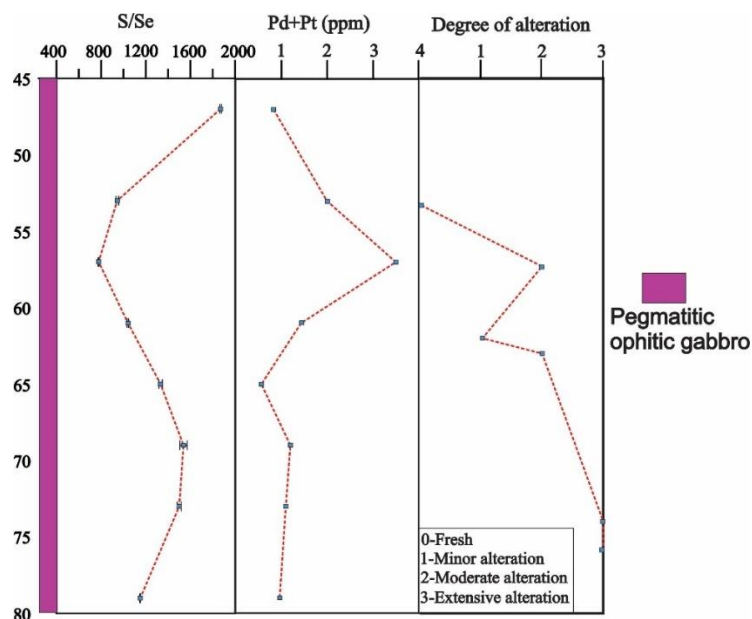

Figure 6-21. Down-hole variation in S/Se, Pt+Pd, and the degree of alteration for PGE well mineralized pegmatitic ophitic gabbro in SL-13-36.

6.7 Discussion

Based on examination of crosscutting and other field relationships, the following sequence of events is proposed to explain the Eastern Gabbro Suite at Area 41.

1. The meta-basalt and feldspathic clinopyroxenite are the earliest igneous events. The latter was initially emplaced as thick sills along Archean unconformity and later intruded preferentially into the Archean meta-sediments
2. Intrusion of the Layered Series as thick sills into the early formed meta-basalt. Copper sulfide mineralization occurs within the Layered Series rocks, but it is typically associated with actinolite and albite alteration and lacks PGE mineralization, similar to the Layered Series at the Marathon deposit (Good et al., 2015) and at Four Dams (see Chapter 3).
3. Intrusion of the ophitic gabbro by multiple pulses of a plagioclase-rich crystal mush that intruded through the meta-basalt and is confined by the footwall. The crystal mush intrusion crystallized three subtypes of ophitic gabbro with

different grain sizes: the medium- grained, the coarse- grained, and the pegmatitic ophitic gabbro.

4. The apatitic clinopyroxenite and oxide melatroctolite intruded along the margin of the feldspathic clinopyroxenite. The oxide melatroctolite typically cuts the coarse-grained ophitic gabbro whereas the apatitic clinopyroxenite cuts the medium- grained ophitic gabbro, and also less commonly footwall.

6.7.1 Sulfur loss

Mantle S/Se values are around 3100 to 3300, *e.g.*, 3333 (McDonough and Sun, 1995), 3300 (Hattori et al., 2002), and 3150 (Lorand et al., 2003). S/Se ratios greater than mantle values are interpreted to be the result of the contamination of the magma by sulfur-rich country rocks, whereas those lower than mantle values can indicate S loss during post-crystallization (Queffurus and Barnes, 2015). Figure 6-20J shows that S/Se ratios of PGE-enriched pegmatitic ophitic gabbro are typically within 500-2000 (1200 in average), below the mantle value, which is consistent with the S loss.

Two processes have been proposed to account for S loss: hydrothermal remobilization (Queffurus and Barnes, 2015) and partial dissolution of the sulfide by a process of ‘multistage-dissolution-upgrading’ (Kerr and Leitch, 2005). The involvement of hydrothermal fluids might be a reasonable interpretation in this case because: 1) sulfide minerals that are rimed by secondary magnetite commonly are surrounded by secondary minerals such as chlorite (Figs. 6-17D and L); and, 2) sulfur has a higher mobility in oxidized hydrous fluids below 300 °C (Queffurus and Barnes, 2015). However, Figure 6-20L shows that the PGE-enriched pegmatitic ophitic gabbro has almost constant Pd/Ir with variable S/Se, this is more consistent with a magmatic process considering the different mobilities of Pd and Ir in hydrothermal fluids (Keays et al., 1982). In addition, the poor correlation between S/Se and the degree of alteration is expected based on their different down-hole profiles (Fig. 6-21). Furthermore, the wave-like down-hole variations of S/Se

throughout around 40 m thick PGE-enriched pegmatitic ophitic gabbro (Fig. 6-21) is hard to explain by the involvement of fluids.

Instead, this pattern more likely reflects multiple injections of magma considering the variable Mg# values exhibited by the ophitic gabbro (Figs. 6-12 and 6-13), which can be linked to another mechanism named sulfide dissolution by a process of ‘multistage-dissolution-upgrading’. The partial dissolution of sulfide may occur when multiple pulses of sulfur undersaturated magmas interact with a sulfide liquid. This process has been modeled by Kerr and Leitch (2005), and the result of this is the upgrading the metal tenors of chalcophile elements that have high partition coefficients into sulfide minerals, such as PGE and Se. Conversely, elements with low partition coefficients such as Fe and S will be preferentially resorbed by the magma. Therefore, the highest tenor sulfides will exhibit the lowest S/Se ratio (Ihlenfeld and Keays, 2011). This is consistent with the broad negative relationship exhibited between S/Se ratios and PGE grades for the PGE-enriched units (Fig. 6-20K).

6.7.2 Possible origins of sulfide mineralization

6.7.2.1 The role of hydrothermal fluids

Some PGE mineralized ophitic gabbro and apatitic clinopyroxenite are moderately to extensively altered by chlorite and actinolite. In addition, some PGM grains are observed within hydrothermal minerals such as chlorite and actinolite (Figs. 6-19I-K). Furthermore, in the PGE-enriched pegmatitic ophitic gabbro we observed the replacement of primary apatite and biotite by later chlorine-rich secondary apatite and biotite (Figs. 6-7 and 6-8), indicating the involvement of chlorine-rich hydrothermal fluids during generation of this unit. These fluids are capable of remobilizing PGE elements (Mathez, 1989; Marshall et al., 1999). These lines of evidence suggest that hydrothermal fluids were potentially important for PGE mineralization at Area 41.

If the hydrothermal mobilization was responsible for the concentration of Cu and PGE, then a positive correlation between the degree of alteration and PGE grades is expected. However, the detailed petrographic work show that some samples with extensive alteration actually contain lower PGE grades than those with negligible-minor alteration (Table 6-9). Furthermore, if PGE elements were concentrated by hydrothermal fluids, the mobilities of PPGE (Pt, Pd, and Rh) are different from IPGE (Ir, Os, Ru) in chlorine-rich fluids. This will result in scatter in correlations between the two groups of PGE elements (Keays et al., 1982; Holwell et al., 2014). However, ratios of Pd /Ir, and Ir / Rh in PGE-enriched samples are almost constant (Figs. 6-20G-I). Therefore, the role of hydrothermal fluids on concentrating PGE is negligible.

Alternatively, hydrothermal fluids may affect PGE mineralization through modification of PGM mineralogy. This role has been attributed by many studies to account for the mineralogical and chemical variations of the PGM in some PGE deposits, *e.g.*, the Merensky reef in the Bushveld Complex (Li et al. 2004), the J-M reef in the Stillwater Complex (Meurer et al., 1999), and Ferguson Lake deposit in Nunavut of Canada (Campos-Alvarez et al. 2012). Typically, the PGM modified by hydrothermal fluids will tend to be enriched in As, Sb, or Te, all are highly mobile elements in hydrothermal fluids. Our results show that As-, Sb-, and Te-bearing PGM such as sperrylite, arsenopalladinite, menshikovite, hollingworthite, mertierite-II, stillwaterite, and telluride are only observed in altered samples (Table 6-9) and are in association with to secondary minerals such as chlorite and actinolite, but also occurs in close proximity to sulfides (Figs. 6-19I-K). Therefore, it is likely that hydrothermal fluids were responsible for the release of PGE from sulfides, but without much transportation prior to the precipitation of PGM with modified mineralogy.

6.7.2.2 Magmatic processes

Most PGM grains are spatially related to sulfide minerals such as chalcopyrite and pyrrhotite (Figs. 6-19A, B, E, and H). In addition, element pairs Pd-Pt, Pd-Ir, Pd-Rh, and Rh-Ir (Figs. 6-20D, G, I, and J) are positively correlated, and there is a negative relationship between S/Se and PGE grades exhibited by the PGE-enriched pegmatitic ophitic gabbro (Fig. 6-20K). Cu- and Pd-enriched subzones also occur in the footwall troughs (Fig. 6-15), which is strong evidence for accumulation of sulfides in flow dynamic traps (Naldrett, 1997; Rice and Moore, 2001; Good et al., 2015). All these are evidence for a magmatic control on PGE mineralization, whereby Cu and PGE were concentrated in sulfide droplets within a magma column.

Three types of mineralization are recognized at Area 41, they are Cu-rich and PGE-poor mineralization (type 1), PGE mineralization (type 2), and Pd (and Pt)-enriched and Cu-poor mineralization (type 3) (Fig. 6-15). The following section evaluates the processes that may have given rise to the different mineralization styles.

6.7.2.2.1 Type 1 Cu-rich and PGE-poor mineralization

Type 1 mineralization is mainly hosted by the coarse-grained ophitic gabbro. It has a low PGE tenor with PGE (Pt+Pd) grade < 0.01 ppm and Cu/Pd > 16000. This can be the result of two possible mechanisms. First, given that sulfide saturation occurred in this system, the high Cu/Pd corresponds to a small R-factor (where R is fraction of silicate melt/fraction of sulfide liquid), e.g., < 100 estimated based on the Cu/Pd vs. Pd diagram from Theriault et al. (1997). In this case, the interaction between silicate melt and sulfide liquid is minor, which suggests a magma system that is not dynamic.

However, Figures 6-12 and 6-13 show that Mg#s of olivine and clinopyroxene and whole-rock Zr of the coarse-grained ophitic gabbro fluctuate. In addition, the sample variabilities of Mg# values are greater in the coarse-grained ophitic gabbro than in the Layered Series and the feldspathic clinopyroxenite. These indicate the coarse-grained ophitic gabbro likely formed by multiple recharge events, i.e., from a

dynamic magma system. Alternatively, the poor PGE tenor of this type of mineralization could have resulted from an early sulfide saturation event. Due to high partition coefficients of PGE elements into sulfides, this earlier sulfide saturation will inevitably drive the residual magma to become PGE depleted. This interpretation may be reasonable considering that the coarse-grained ophitic gabbro sits stratigraphically above the pegmatitic ophitic gabbro which hosts the PGE-enriched type 3 mineralization (Fig. 6-15).

6.7.2.2.2 Type 2 PGE mineralization

Type 2 PGE mineralization is mainly hosted by the apatitic clinopyroxenite. The high abundance (up to 50 modal %) of apatite in this rock is significant given that apatite is typically an associate or minor phase in gabbroic rocks. Since apatite is denser ($\sim 3.19 \text{ g/cm}^3$, www.webmineral.com) than plagioclase ($\sim 2.68 \text{ g/cm}^3$, www.webmineral.com), a likely interpretation for formation of this cumulate rock is the mechanical settling of apatite during magma ascent particularly if the magma was slowed when conduits are more restricted. This mechanism was also proposed by Tollari et al. (2008) to explain the presence of nelsonite in the Sept-Iles intrusive suite, Quebec, and by Good et al. (2015) to explain the apatite-rich intrusions at the Marathon deposit.

From a mass balance perspective, the volume of magma required to produce this unit would have been much greater than the volume of the current cumulate rock. This unit has mantle range of Cu/Pd (1000-10000), reflecting small variations in R-factor, e.g., vary between 1500-10000 based on the Cu/Pd vs. Pd diagram from Theriault et al. (1997). Therefore, the apatitic clinopyroxenite might have formed by one single pulse of magma, and thus the associated type 2 PGE mineralization may be related to a mechanism whereby PGE mineralization is controlled by the accumulation of sulfides from magma in a relatively simple closed system. In this scenario, PGE tenor of sulfide minerals is governed by partition coefficients of Cu and Pd between silicate melt and sulfide liquid, and also by the R-factor, without

any further upgrading. The small variations in R-factor for this type mineralization suggest a turbulent setting for the single magma intrusion, through which, the segregated sulfide droplets were suspended and disproportionally interacted with silicate melts prior to the settlement.

5.7.2.2.3 Type 3 PGE-enriched mineralization

Type 3 mineralization is mainly hosted by the pegmatitic ophitic gabbro. This unit has fluctuating down-hole variations in Mg#s of olivine and clinopyroxene and whole-rock Zr, as well as more variable Mg# values compared to other units (Figs. 6-12 and 6-13). Both are evidence suggesting that it formed in a dynamic system that involves multiple intrusions. This is consistent with the observed replacement of earlier plagioclase by later more calcic plagioclase in the pegmatitic ophitic gabbro (Fig. 6-6). Similar textures were interpreted by Good and Crocket (1994) and Shahabifar Far (2016) as indicative of magma recharge in a conduit system.

Cu/Pd ratios for this mineralization typically vary from < 100 to 1000 , which corresponds to extremely high R-factors ($>10^5$) based on the Cu/Pd vs. Pd diagram from Theriault et al. (1997). The mechanism to attain such high R-factors is likely related to a conduit-type dynamic magma system where Pd plus Pt tenors of sulfide minerals were progressively increased through a process of multistage dissolution upgrading, which is supported by the low S/Se ratio. This process generally involves: 1) the segregation of sulfide liquids likely due to the lowering of temperature, 2) enrichment of sulfide droplets with PGE during turbulent interaction between sulfide melt and magma within the conduit system, 3) upgrading of sulfide metal tenor when sulfide droplets were suspended and interacted with later pulses of sulfide undersaturated magma, which resulted in the dissolution of sulfide and increase of PGE tenor in the sulfide droplet, and, 4) settling of PGE-enriched sulfide liquid in a staging chamber.

6.7.3 Evidence for the feeder channel

The topography of Area 41 has deeply eroded lineaments striking in different directions (Fig. 6-2). Lineaments are commonly observed at the topography of the Coldwell Alkaline Complex. Mitchell and Platt (1982) and Walker et al. (1993) related formation of lineaments to at least two stages of faulting resulted by either the Cauldron subsidence during the formation of the Coldwell Alkaline Complex, or late block faulting at the end of formation of the Complex. This proposed fault history was consistent with observations of Good et al. (2015) at the Marathon deposit, and also agrees with observations at Area 41 that magma intruded along the earlier faulting event.

A 3D geological model (Fig. 6-22) was constructed using GOCAD^R to investigate the possible locations of magma feeder channels. It shows that there is a north south keel-shaped trough located below the drill hole SL-13-32 (and SL-13-31). Figure 6-2 shows that two major surface lineaments crosscut approximately at the collar of SL-13-32 (and SL-13-31), indicating a faulting setting around this trough. This trough is also filled with the thickest zone of the Marathon Series rocks (Fig. 6-3A), indicating the Marathon Series magma may initially emplace at the location of this trough. Furthermore, the occurrence of the apatitic clinopyroxenite is accumulated in, or in proximity to, this trough (Fig. 6-3A). Owing to the high density of apatite, it is reasonable to assume that the high concentration of apatite settled from the magma in the conduit during ascent. Good et al. (2015) also found that there was a close spatial relationship between the location of feeder channels and the prevalence of apatite and magnetite cumulate rocks at the Marathon deposit. Taken together, this evidence suggests the trough in the footwall is a feeder channel.

To further investigate the intrusive and spatial relationships near the trough, Figure 6-22 shows variations in thickness of the Marathon Series package, and the relative proportions of pegmatitic ophitic gabbro, breccia units, mineralized zones, apatitic clinopyroxenite, and oxide melatroctolite along a longitudinal section. Note that this

longitudinal section involves 21 representative drill holes at Area 41. The progressive decrease in these parameters away from drill hole SL-13-32 (and SL-13-31) is consistent with a scenario where magma intrusions emplaced through the feeder channel in proximity to SL-13-32, and then flowed away as sills in different directions. In addition to the feeder channel close to SL-13-32, the spatial variations suggest a feeder channel is located at the east end of this longitudinal section (Fig. 6-22). Note that drill hole SL-13-32 contains the type 3 mineralization which is interpreted to be likely related to be a conduit-type deposition (see section 6.7.2.2), the confirmation of a feeder zone close to this drill hole thus establish the relationship between the PGE mineralization and the conduit system.

Figure 6-22. Spatial variations of the thickness of the Marathon Series rocks, the proportion of pegmatitic ophitic gabbro, the proportion of the breccia units, the proportion of mineralized Marathon Series units, the proportion of the apatitic clinopyroxenite, and the proportion of the oxide melatroctolite. The 3D model illustrates the stratigraphy of Area 41, and red lines on the cartoon represent drill holes. Drill holes are indicated using red infilled circles on the longitudinal line, potential feeder channels are indicated using the black rectangles.

6.7.4 Comparisons to the Marathon deposit and implications to mineral exploration

The Marathon deposit is the largest and best explored deposit within the Coldwell Alkaline Complex. Its PGE mineralization was defined as a contact-type by Barrie et al. (2002). However, based on well documented field, petrographic, and geochemical evidence, Ruthart (2013) and Good et al. (2015) proposed a conduit model to interpret its PGE mineralization. Four zones of PGE mineralization recognized at the Marathon deposit: Main zone, Footwall zone, Hanging-wall zone, and an extremely PGE enriched zone named W-Horizon. The Main zone and W-Horizon are of particular economic interest. The Main zone has Cu/Pd ratios typically within 1000-10000 (mantle range). It was interpreted by Good et al. (2015) to form by a closed system R-factor model within the conduit system, which is similar to the type 2 PGE mineralization at Area 41. The only difference between the two is their host units, i.e., the Two Duck Lake gabbro at the Marathon deposit whereas the apatitic clinopyroxenite at Area 41. The W-Horizon is characterized by an extreme enrichment in Pd plus Pt relative to Cu ($\text{Cu/Pd} < 1000$), and S/Se (800 in average) (Ruthart, 2013; Good et al. 2015). Ruthart (2013) proposed that the W-Horizon formed by a ‘multistage dissolution upgrading’ process in a very dynamic system. The geochemical characteristics and the proposed deposition model for W-Horizon are similar with those for type 3 mineralization at Area 41.

The roughly 18-km Eastern Gabbro suite between the Marathon deposit and the Area 41 lacks mappable, continuous stratigraphic horizons, but both areas display similar types of PGE mineralization hosted by generally similar lithologies. The importance of conduit settings for PGE mineralization at both the Marathon deposit and Area 41 is that other conduits and associated PGE mineralization may occur elsewhere in the Eastern Gabbro. Recognition of this is significant because the conduit model predicts that mineralization can occur at any Marathon Series stratigraphic horizon in the Eastern Gabbro, and may contain disseminated to massive sulfides that have variable Cu/Pd and metal tenors. Furthermore, of

particular interest is that the conduit-related model also predicts the possibility for extreme PGE concentrations as a result of upgrading by a ‘multistage dissolution upgrading’ process, as already demonstrated by the W-Horizon at the Marathon deposit and type 3 PGE mineralization at Area 41.

6.8 Conclusions

This contribution integrates petrography, whole-rock and mineral chemistry, and 3D modeling to comprehensively characterize the igneous stratigraphy and Cu-Pd mineralization at Area 41. Important conclusions are:

- (1) The units of the Eastern Gabbro assemblage are composed of three series: metabasalt, the Layered Series, and the Marathon Series, the same as those observed at the Marathon deposit.
- (2) Cu-Pd mineralization at Area 41 is hosted by the Marathon Series, particularly a pegmatitic ophitic gabbro. Lab-based and field portable instruments-based results show that at Area 41 the Marathon Series is geochemically distinctive with the metabasalt and Layered Series, which forms a significant component for mineral exploration.
- (3) Three types of sulfide mineralization are identified at Area 41. Type 1 is the Cu-rich and PGE-poor mineralization mainly hosted by the coarse-grained ophitic gabbro, which likely formed by an early sulfide saturation event. Type 2 is the PGE mineralization mainly hosted by the apatitic clinopyroxenite, which is interpreted to form by a closed R system. Type 3 is the PGE-enriched mineralization, which is proposed to form by a ‘multi-stage dissolution upgrading’ process in a conduit system. The 3D modeling confirms the presence of magma feeder channel at Area 41.
- (4) Overall, mineralization at Area 41 is similar with that at the Marathon Cu-Pd deposit, both are related to a conduit-type deposition, suggesting that mineralization in all probability elsewhere in the Coldwell Alkaline Complex is conduit-related.

Recognizing this will increase the potential for discovery high grade deposits in the Coldwell Alkaline Complex.

Chapter 7

Discussions and Conclusions

7.1 Discussions

Petrography, lithogeochemistry (pXRF- and lab-based), geochemical modeling, 3D modeling, and mineral chemistry (bSEM-EDS- and electron microprobe-based) were applied as main means in this thesis to address the three main problems as set up in Chapter 1. The overall objective of this project was to: 1) develop a field-suitable exploration tool to help mineral exploration at the whole Coldwell Alkaline Complex, 2) examine the genesis of the Layered Series and its relevance to PGE mineralization, and, 3) develop a general exploration model applicable for the whole Coldwell Alkaline Complex. The successful accomplishment of the goal in this thesis will provide at least three implications for mineral exploration, as well as the understanding of geology and associated Cu-PGE mineralization, in the Coldwell Alkaline Complex and elsewhere.

7.1.1 Implications of mineral exploration

This thesis demonstrated that the pXRF and bSEM-EDS results can be applied to explore for Cu-Pd along the entire Eastern Gabbro package in the Coldwell Alkaline Complex by measuring aspects that are consistent with the deposit model, such as: 1) high Cu/S ratios as a vector to mineralization; 2) identification of platinum group minerals in favorable magma recharge zones; and, 3) inter element ratios that help to distinguish the Marathon Series from the Layered Series.

Since Platinum-group elements, particularly Pd and Pt, tend to preferentially partition into the Cu-rich residual liquid after MSS crystallization (Howell and McDonald, 2010). Provided that the magmatic sulfide liquids fractionated MSS, Pd and Pt would be concentrated in areas where Cu-rich sulfide minerals, such as chalcopyrite, cubanite, and bornite, are abundant, all of which have high Cu/S ratios. Barnes and Ripley (2016) also suggested that the Cu-rich ores are normally enriched

in Pd and Pt. Examples of PGE mineralization concentrated in high Cu-rich ores include the PGE-enriched sulfide horizons at the Dunka Road Cu-Ni-PGE deposit at the Duluth Complex, which are typically composed of intergrown chalcopyrite, cubanite, and pentlandite, with less abundant pyrrhotite (Theriault et al., 1997), and the Platinova Reef in the Skaergaard Intrusion where magmatic sulfide minerals are present as a Cu-rich, Fe-poor assemblage (Nilsen, 2001). It is thus reasonable to suggest that high Cu/S proxy as an exploration tool may also be applicable to other PGE-dominated deposits. This indicates that pXRF can be used to explore for Cu-PGE at other settings.

In addition, magma recharge is considered favorable for PGE mineralization because: it implies the existence of a magma conduit setting, whereby PGE mineralization can be controlled by various fluid dynamic processes (Marsh, 2006), and, 2) the sulfide tenor can be gradually upgraded through a magma recharge process (Kerr and Leitch, 2005), thus increasing the potential for discovery of high-grade deposits. Therefore, using the combination of pXRF and bSEM-EDS to envisage magma conduits as an exploration tool may also be applicable to PGE deposits in other settings.

At least, but not least, geochemically mapping the igneous stratigraphy is key to mineral exploration at elsewhere, not only limited to PGE-related deposits, but also may apply to other types of deposits. This is particularly true when mineralization is only hosted by certain stratigraphic horizons that are geochemically distinctive with other horizons. For example, the Tamarack magmatic sulfide deposit consists of two intrusive units such as fine-grained olivine and coarse-grained olivine intrusions, but the latter is a preferable host to mineralization (Taranovic et al., 2016). The thesis has demonstrated the considerable promise of using pXRF and bSEM-EDS to map the igneous stratigraphy at the Coldwell Alkaline Complex, both techniques can be combined to map the igneous stratigraphy at other complex settings to serve mineral exploration.

7.1.2 Implications for petrogenesis of the layered gabbro

Portable XRF and bSEM-EDS results show that the Layered Series at Four Dams and Area 41 has different fractionation trends, indicating different processes occurred for the Layered Series at different locations of the Eastern Gabbro. This aroused an academic interest regarding the development of the Layered Series, which were further examined by applying lab-based results in this thesis. This means that the combination of pXRF and bSEM-EDS also can be combined to improve hypothesis testing regarding the petrogenesis of intrusions from elsewhere.

It has long been assumed that the layered rocks represent an upward-aggrading piles of crystals deposited on the floor of a vast, long-lived magma chamber (Wagner, 1929; Cameron, 1980; Kruger, 2005). However, over the past decade a new concept that challenges this long recognized model has been growing, which suggests that the ultramafic layers formed by out-of-sequence injection of thin sills into order mafic layers (Mitchell and Scoon, 2007, 2012; Mungall et al., 2016). Mungall et al. (2016) examined the Rustenburg Layered Suite of the enormous Bushveld Igneous Complex using U-Pb geochronology and suggested that it formed within a stack of discrete sheet-like intrusions emplaced and solidified as separate bodies beneath older layers. The current study suggests that the Layered Series at the Coldwell Alkaline Complex formed by multiple intrusions within a conduit system, which provides a good example to the new school of recognition regarding the development of large layered intrusions. In addition, this thesis also has discussed possible reasons for the lack of PGE mineralization of the Layered Series that formed in magma conduits. Since magma conduits are favorable for PGE mineralization (Naldrett, 1999), the study of the Layered Series thus is a notable example showing that magma conduits do not necessarily form the PGE mineralization, other factors such as the source of magma intrusions and mechanisms during magma emplacement (e.g., early sulfide saturation) should also be considered.

7.1.3 Implications for PGE mineralization

The magma conduit model has grown in favor since it was proposed for gabbro-hosted deposits in the Norilsk region, Siberia, by Naldrett et al. (1995) and Naldrett and Lightfoot (1999), to account for the enrichment of PGE relative to Cu and Ni in disseminated sulfide minerals. Acceptance of the dynamic conduit model for formation of PGE-related deposits by far was almost universal, notable examples include Jinchuan (Naldrett, 1999), Eagle Intrusion (Ding et al., 2012), River Valley Intrusion (Howell et al., 2014). In this thesis, a general conduit model also has been proposed to explain the PGE mineralization at the whole Coldwell Alkaline Complex. It is therefore a good example showing the applicability of the conduit model in terms of explaining PGE mineralization in a complex setting.

In addition, PGE mineralization discussed in this study is hosted by the Coldwell Alkaline Complex consisting of gabbroic to syenitic units, this is in contrast to most PGE deposits that are hosted by mafic-ultramafic complexes. Since many PGE-related deposits hosted within mafic-ultramafic complexes have been proposed to be related to magma conduits, the formation of PGE mineralization in the alkaline complex thus is similar with that in mafic-ultramafic intrusions.

7.2 Conclusions

Corresponding to the three main questions as mentioned in Chapter 1, the main conclusions for this thesis are summarized as follows.

- (1) pXRF and bSEM-EDS can be combined as an exploration tool to help mineral exploration at the entire Coldwell Alkaline Complex and may also be applicable to PGE-related deposits in other settings.
- (2) The Layered Series developed by multiple intrusions in a dynamic system. However, it is not co-genetic with the Marathon Series and perhaps has undergone an early sulfide saturation event, which resulted in its PGE-barren nature.
- (3) Cu-Pd mineralization in Area 41 can be explained by a conduit-model, which is similar to mineralization in the Marathon deposit. This indicates that other potential

PGE mineralized zones in the Coldwell Alkaline Complex perhaps are also conduit-related.

CONTRIBUTIONS TO ORIGINAL KNOWLEDGE

- 1) This is the first study that combines pXRF and bSEM-EDS as an exploration tool in a complex geological setting. This method was then tested for the complex as a whole.
- 2) This is the first study that examined the parental magma of Layered Series within the Eastern Gabbro and investigated its relationship with the Coubran basalts using geochemical modeling.
- 3) This is one of a small number of investigations that examined origins of both the decoupled and coupled magma reverse evolutions for the Layered Series intrusions, and related them to magmatic processes occurred in the magma chamber.
- 4) This is the first study of Area 41 PGE mineralization. The recognition of a conduit system at Area 41 is encouraging for the exploration of other conduits in the Coldwell Alkaline Complex.
- 5) To our knowledge, this study is one of a small number of investigations that have studied the origin of PGE mineralization hosted by a gabbro-alkaline complex.

RECOMMENDATIONS FOR FUTURE WORK

This study has characterized the Layered Series in great detail, but there are still some problems remain unresolved. First, the Layered Series parental magma can not be directly related to the Coubran basalts, but it has similar compositions with $F=0.55$ residual melt of the Coubran basalts. It is not certain if there is another basalt candidate within the Coldwell Complex that can be related to the parental magma

of the Layered Series units. Further, it is expected that if such a basalt candidate is present, it may have a relationship with the Coubran basalts, but the origin of the Coubran basalts is still poorly constrained.

Another special rock type (the Malpas Lake Intrusion) which has almost the same petrographical characteristics with the Layered Series unit is distinguished by its unique geochemical characteristics. Results show that the Malpas Lake Intrusion is even more evolved than the Layered Series units and seems to have some relationships with the syenites, but the syenites are the youngest rock unit in the Coldwell Complex. However, during the course of this thesis, it still has not been well characterized particularly with respect to the origin. Future work on this Intrusion is suggested.

A conduit system is interpreted to be close to drill hole SL-13-32 at Area 41. The inspection of thin sections shows that the Marathon Series units at this drill hole were more extensively altered than units intersected by other drill holes at Area 41. Particularly, chlorine-rich apatite and biotite were observed in the ophitic gabbro rocks in SL-13-32. It can therefore be hypothesised that the conduit system might have facilitated the flow of chlorine-rich fluids, which modified the PGE mineralization. If this is correct, there should be consistent spatial variations in the degree of alteration as well as the chances for observations of As- and Te- rich PGM away from the conduit. It would be worthwhile to investigate this possibility using more detailed petrography. In addition, electron microprobe analyses show that the chlorine-rich biotite contains higher than 1 wt.% chlorine (it can be treated as a major element), it is unclear whether this biotite crystallized from magmatic fluids from the Coldwell Alkaline Complex or from other fluids of an unknown nature.

Appendices

Appendix 1: Copyright permission for Chapter 2 “The application of portable XRF and benchtop SEM-EDS to Cu-Pd exploration in the Coldwell Alkaline Complex, Ontario, Canada”.

Subject: RE: GEEA paper

Dear Yonghua,

Yes, thanks for asking – that is fine.

Here is the wording from our website:

Authors may re-use their own material without permission subject to the exceptions listed below. They may include the whole article in a PhD or other thesis provided that it will not be published, and that the original source is fully acknowledged in the standard form. If the thesis is to be included in the institution’s electronic repository or other online host, authors must use their own finally accepted version, not the typeset PDF (unless it is [Gold Open Access](#)). Authors may not re-publish their whole article, or a substantial part of it, without permission. Such permission will be granted only in exceptional circumstances.

Good luck in your viva!

With best wishes,

Jessica

Appendix 2: List of all powdered samples that have done portable XRF and/or ICP-AES/MS/IR analyses.

Appendix 4. pXRF whole-rock analyses. Unit for major oxides (except MnO) is weight percent, unit for others is ppm. Major oxides were determined using the mining mode, and trace elements were determined using the soil mode. Numbers given below oxides (and elements) are 95% confidence analytical precision determined by repetitive analyses. Symbols for rocks: 2a-meta-basalt, 2i-feldspathic clinopyroxenite, 2b-olivine gabbro, 2f-oxide augite melatroctolite, 3a-medium-grained ophitic gabbro, 3b-coarse-grained ophitic gabbro, 3d-pegmatitic ophitic gabbro, 3g-oxide melatroctolite, 3h-apatitic clinopyroxenite, 3i-apatitic olivine clinopyroxenite, MLI-malpas lake intrusion. Samples begin with FD, SL, and MS were sampled at drill holes at Four Dams, Area 41 and WD zone, respectively.

Appendix 5. Laboratory-based whole-rock analyses. Unit for major oxides, S, and C is weight%, unit for trace elements is ppm. Major elements were determined by ICP-AES, trace elements were determined by ICP-MS, both after lithium borate fusion on a minimum 2 g of pulp samples. Total S was determined using a Leco combustion furnace on 0.01-0.1 g of sample, ferrous Fe was determined by H2SO4-HF acid digestion and titration on 1 g of sample. Symbols for rocks: 2i-feldspathic clinopyroxenite, 2b-olivine gabbro, 2f-oxide augite melatroctolite, 3b-ophitic gabbro, 3g-oxide melatroctolite, 3h-apatitic clinopyroxenite, 3i-apatitic olivine clinopyroxenite, MLI-malpas lake intrusion. Samples begin with FD, SL, and MS were sampled at drill holes at Four Dams, Area 41 and WD zone, respectively.

Curriculum vitae

Mr. Yonghua Cao (Ph.D.)

Born in June, 1987

Education Since 2005

2012-January, 2017

- Ph.D. candidate at Department of Earth Sciences, Western University, Canada.

2009-2011

- M.Sc. at School of Geosciences and Info-Physics, Central South University (CSU), China.

2005-2009

- B.Sc. at School of Geosciences and Environmental Engineering, Central South University (CSU), China.
-

Courses taken at Western University

- Graduate Seminar, 86/100
 - Advance mineral deposit geochemistry, 88/100
 - Best practices in exploration drilling, 90/100
-

Teaching Experiences

- Earth Rocks (Teaching assistant, 2012)
 - Life on Planet Earth (Teaching assistant, 2013)
 - Catastrophic Events in Earth History (Teaching assistant, 2014-15)
 - bSEM training (serve as the bSEM technician, 2013-present)
-

Research Experiences

2013-present

- Cu-Pd mineralization and exploration geochemistry of the northeastern portion of the Coldwell Complex, Ontario, Canada. (**Ph.D. thesis, funded by NSERC and China Scholarship Council**).

2012-2013

- Mineralization in the Young-Davidson gold deposit, Matachewan, Ontario, Canada.

2009-2011

- Characteristics of Ore-forming Fluids and Mineralization in the Dehelongwa Cu (Au) deposit, Tongren, Qinghai Province. (**M.Sc. thesis**)
- Evaluation of prospecting target in Kusilapu Copper-Lead-Zinc Metallogenic Belt, West Kunlun, Xinjiang, China.

2008-2009

- Characteristics of ore-bearing sedimentary rocks in the Saishitang Copper Mine Area, Qinghai, China. (**B.Sc. thesis**).

2007-2008

- Leader of Innovative Experimental project funded by Central South University, title of the project is “Geological Characteristics and Genesis of Yixingzai Au deposit, Sanxi, China”.

Main Articles

(1) Published journal and conference papers

- Yonghua Cao, Robert Linnen, David Good, Iain Samson, Rachel Epstein. 2016. The application of portable XRF and benchtop SEM-EDS to Cu- Pd exploration in the Coldwell Alkaline Complex, Ontario, Canada. *Geochemistry: Exploration, Environment, Analysis*, 16, 193-212.
- Yonghua Cao, Robert Linnen, David Good, Iain Samson: Advancing Field Portable Techniques in Exploration by Combining pXRF and Benchtop SEM (bSEM): A Case Study of the Igneous Stratigraphy and Cu-Pd Mineralization of the

Eastern Gabbro of the Coldwell Alkaline Complex, Ontario, Canada. In Mineral Resources in a Sustainable World, 13th SGA Biennial Meeting, Nancy, France. A.-S. André-Mayer, M. Cathelineau, P. Muchez, E. Pirard and S. Sindern eds., v. 3, 901-904.

(2) Conference abstracts

- Yonghua Cao, Robert Linnen, David Good, Iain Samson: Igneous stratigraphy and Cu-Pd mineralization at Area 41 within the Eastern Gabbro of the Coldwell Alkaline Complex, Canada. GAC-MAC2016 Whitehorse; 06/2016.
- Yonghua Cao, Robert Linnen, David Good, Iain Samson: The application of pXRF and benchtop SEM (bSEM) to characterize the igneous stratigraphy and Cu-Pd mineralization in the Eastern Gabbro, Coldwell Alkaline Complex. 2015 Joint Assembly; 05/2015.
- Yonghua Cao, Robert Linnen, David Good, Iain Samson, Matthew Brzozowski: The study on the igneous stratigraphy and mineralization at the Eastern Gabbro, Coldwell Complex: a combination of the benchtop SEM and pXRF. Mineral Exploration Roundup; 01/2015.
- Yonghua Cao, Robert Linnen, David Good, Charles Wu, Iain Samson: Application of pXRF to Cu grade estimation and igneous stratigraphy characterization: A case study at the north edge of the Eastern Gabbro, Coldwell Alkaline Complex, Canada. GAC-MAC; 05/2014.
- Yonghua Cao, Robert Linnen, David Good, Iain Samson: Application of pXRF to Cu grade estimation and igneous stratigraphy characterization: A case study at the north edge of the Eastern Gabbro, Coldwell Alkaline Complex, Canada. PDAC-SEG students mineral Colloquium; 03/2014.

(3) Papers in preparation

- Yonghua Cao, Robert Linnen, David Good, Iain Samson. Igneous stratigraphy and Cu-Pd mineralization at Area 41 within the Eastern Gabbro, Coldwell Alkaline Complex, Canada. (In preparation, to be submitted to <Economic Geology>).
- Yonghua Cao, Robert Linnen, David Good, Iain Samson. Characteristics and development of the Layered Series in the Eastern Gabbro, Coldwell Alkaline Complex, Ontario, Canada: constraints from geochemical modelling. (In preparation, to be submitted to <Journal of petrology>).

Other Activities

- Structure Economic Geology in Mineral Exploration workshop, Western University, 2013.
- Gocad 3D modeling workshop, Western University, 2015.
- Leapfrog 3D modeling short course, Western University, 2016.
- SEG student membership, 2013-2016
- APGO student membership, 2013-2015
- GAC student membership, 2013-2016
- CIM student membership, 2013-2016

Honors and Scholarships

- ‘China Scholarship Council’ scholarship (2012-2016).
- Mineral Deposit Division (MDD) grant (2016).
- Teaching assistantship (2012-2016)
- Research assistantship (2014-2017)
- Won the best M.Sc. thesis prize at CSU (2011).
- Scholarship of Academic Excellence for three years (2006~2008).
- Won the first Prize of undergraduate thesis Design (2009).
- Received “excellent graduate” prize at CSU (2009).
- Chinese National Endeavor Fellowship (2007).

- Chinese National scholarship (2006).
-

Computer Skills

- Fluent in Photoshop, IoGas, AutoCAD, Grapher, CorelDraw, Σ -plot, Microsoft Office (Word/Excel/PowerPoint), Igpet
 - 3D modelling programs: Gocad, Leapfrog, MapInfo (discover 3D)
-

Language

- Chinese (mother language)
 - Fluent in English (written, speaking, listening)
-
